Intellectual Property Rights

IPRs essential or potentially essential to the present document may have been declared to ETSI. The information pertaining to these essential IPRs, if any, is publicly available for **ETSI members and non-members**, and can be found in ETSI SR 000 314: "*Intellectual Property Rights (IPRs); Essential, or potentially Essential, IPRs notified to ETSI in respect of ETSI standards*", which is available from the ETSI Secretariat. Latest updates are available on the ETSI Web server (<http://webapp.etsi.org/IPR/home.asp>).

Pursuant to the ETSI IPR Policy, no investigation, including IPR searches, has been carried out by ETSI. No guarantee can be given as to the existence of other IPRs not referenced in ETSI SR 000 314 (or the updates on the ETSI Web server) which are, or may be, or may become, essential to the present document.

Foreword

This Technical Report (TR) has been produced by ETSI Technical Committee Reconfigurable Radio Systems (RRS).

1 Scope

The present document is a study item that can be used in the normative process within ETSI TC RRS, when defining normative system requirements, architecture, and interfaces for Mobile Device (MD) Software Defined Radio (SDR).

The TR 102 680 [i.1] presents a reference architecture for Software Defined Radio (SDR) mobile devices from a *radio computer* viewpoint. Such a device can run radio applications on shared platform resources, and install new ones even during run-time, much like a personal computer with regular computer programs. The reference architecture details the internals of a possible mobile device SDR subsystem, but is not meant to be a normative architecture. Instead, it identifies various key interfaces that may be generalized in order for the multiradio computer vision to be realized. These interfaces may be normative.

SDR can be on one hand considered as an implementation technology that replaces legacy ASICs when suitable cost and power tradeoffs can be found; this track is not in the scope of ETSI TC RRS. On the other hand, SDR can be considered as an enabling technology for Cognitive Radio (CR) systems. It is in the scope of ETSI TC RRS to define the responsibilities of various subsystems in a complete CR system. The TR 103 062 [i.2] lists high level use scenarios for SDR based mobile devices, to be used in this process.

The two approaches meet at the interface to the SDR subsystem. This is called the Multiradio Interface (MURI) in the reference architecture. The purpose of this technical report is to outline the functionality at this interface, both from SDR technology and CR system perspectives. The use scenarios are analyzed first, in order to partition the responsibilities between the SDR subsystem and the CR entities on top of it. Then the SDR subsystem is taken a deeper look, based on TR 102 680 [i.1] and technology deployment scenarios. Finally the MURI functionality is sketched from these basis.

2 References

References are either specific (identified by date of publication and/or edition number or version number) or non-specific. For specific references, only the cited version applies. For non-specific references, the latest version of the referenced document (including any amendments) applies.

Referenced documents which are not found to be publicly available in the expected location might be found at <http://docbox.etsi.org/Reference>.

NOTE: While any hyperlinks included in this clause were valid at the time of publication ETSI cannot guarantee their long term validity.

2.1 Normative references

The following referenced documents are necessary for the application of the present document.

Not applicable.

2.2 Informative references

The following referenced documents are not necessary for the application of the present document but they assist the user with regard to a particular subject area.

- [i.1] ETSI TR 102 680: "Reconfigurable Radio Systems (RRS); SDR Reference Architecture for Mobile Device".
- [i.2] ETSI TR 103 062: "Reconfigurable Radio Systems (RRS) Use Cases and Scenarios for Software Defined Radio (SDR) Reference Architecture for Mobile Device".

3 Definitions and abbreviations

3.1 Definitions

For the purposes of the present document, the following terms and definitions apply:

mobile device: personal communication device (e.g. mobile phone, PDA, laptop PC, etc.) capable of communicating either locally (e.g. Bluetooth), through a network (e.g. GSM) or both by using one or more radio technologies

radio application: software application executing in a software defined multiradio equipment

NOTE: Radio application is typically designed to use certain radio frequency band(s) and it includes agreed schemes for multiple access, modulation, channel and data coding as well as control protocols for all radio layers needed to maintain user data links between adjacent radio equipments, which run the same radio application.

radio equipment: equipment using radio technology

radio system: system which consists of a number of radio equipments using at least one common radio technology

software defined multiradio: device or technology where multiple radio technologies can coexist and share their wireless transmission and/or reception capabilities, including but not limited to regulated parameters, by operating them under a common software system

NOTE 1: Examples of the regulated parameters are frequency range, modulation type, and output power.

NOTE 2: Common software system represents radio operating system functions.

NOTE 3: This definition does not restrict the way software is used to set and/or change the parameters. In one example, this can be done by the algorithm of the already running software. In another example, software downloading may be required.

software defined radio: radio in which the RF operating parameters including, but not limited to, frequency range, modulation type, or output power can be set or altered by software, and/or the technique by which this is achieved

NOTE 1: Excludes changes to operating parameters which occur during the normal pre-installed and predetermined operation of a radio according to a system specification or standard.

NOTE 2: SDR is an implementation technique applicable to many radio technologies and standards.

NOTE 3: SDR techniques are applicable to both transmitters and receivers.

software defined radio equipment: radio equipment supporting SDR technology

3.2 Abbreviations

For the purposes of the present document, the following abbreviations apply:

ASIC	Application Specific Integrated Circuit
BB	BaseBand
CF	Cognitive Functionality
CM	Configuration Manager
CR	Cognitive Radio
DVB:	Digital Video Broadcasting
EMC	Electro-Magnetic Compatibility
FC	Flow Controller
FEM:	Front End Module
FM:	Frequency Modulation
GGSN	Gateway GPRS Support Node
GPRS	General Packet Radio System
GPS:	Global Positioning System
GSM	Global System for Mobile communications

HSxPA: High Speed Packet Access
 HW HardWare
 IP Intellectual Property

NOTE: As in semiconductor IP.

IP Internet Protocol

NOTE: As in TCP/IP.

LTE Long Term Evolution
 MAC: Medium Access Control
 MD Mobile Device
 MRC MultiRadio Controller
 MURI MUltiRadio Interface

NOTE: Renamed from "Multiradio Access Interface" in [i.1].

PDA Personal Digital Assistant
 PDP Packet Data Protocol
 RAT Radio Access Technology
 RCM Radio Connection Manager
 RF Radio Frequency
 RFFI Reconfigurable RF Interface
 RM Resource Manager
 RPI Radio Programming Interface
 RRS Reconfigurable Radio System
 SDR Software Defined Radio
 SMS Short Message Service
 SSID: Service Set Identifier
 SW: Software
 TCP Transport Control Protocol
 TRx: Transceiver
 UMTS: Universal Mobile Telecommunications System
 URA Unified Radio Application
 URAI Unified Radio Application Interface
 WCDMA Wideband Code Division Multiple Access
 WLAN Wireless Local Area Network

4 Use scenarios for SDR based mobile devices

High level use scenarios for SDR based mobile devices have been collected in [i.2]. These use cases are used to define system requirements for SDR mobile devices but not in the scope of the present document; the focus here is in drawing the mobile device SDR architecture and responsibilities for the architectural components. The high level use scenarios are:

- **Terminal-centric configuration in a heterogeneous radio context.** In this scenario, the mobile device is able to detect a heterogeneous wireless framework, consisting of cellular systems, wireless local area networks, wireless personal area networks, etc. Based on its configuration capabilities, it selects a single RAT or multiple RATs to camp on.
- **Network driven terminal configuration in a heterogeneous radio context.** Similarly as in the previous scenario, the mobile device operates on a heterogeneous wireless framework, but here a network decides which RATs the mobile device uses.
- **Addition of new features, such as support for novel radio systems, to mobile devices.** In this scenario, the mobile device is being updated with a new radio application, to support e.g. a novel radio standard.
- **Provision of a new cognitive feature.** In this scenario, the mobile device is being updated with a new cognitive feature, such as cross-technology spectrum measurement.

4.1 Mobile device functionality

Each of the use scenarios is analyzed, and the functionality in the scenario description and the information flow diagrams is expanded from the mobile device perspective.

4.1.1 Power on

Applicable to all usage scenarios.

The mobile device activates suitable RATs for the scenario. Not all RATs may be needed in all scenarios so they may remain inactive. The RATs that are activated start operating as per their radio standard.

The RATs that are not needed may be later deactivated, so they stop consuming power and platform resources.

4.1.2 Context provisioning

Applicable to the terminal and network centric configuration of mobile device scenarios.

The mobile device uses one or more of the active RATs to receive context information from a network (Cognitive Pilot Channel) or by inter-mobile communication. For this the mobile device needs to detect the availability of the network or other suitable mobile devices.

NOTE: Context information within integrated framework (such as 3GPP GSM, UMTS, HSxPA, LTE, LTE-Advanced) is not in the scope of the present document and the information exchange is handled by the corresponding RAT without implications on the SDR architecture.

4.1.3 Link selection

Applicable to the terminal and network centric configuration of mobile device scenarios.

The mobile devices selects one or more of the active RATs in order to form a communication link with a network or other mobile devices. For this the mobile device needs either up-to-date context information or its own sensing results. The selection criteria may include both network centric control schemes as well as autonomous operation by the mobile device.

NOTE: Only the selection of links between distinct systems which are not within an integrated framework (such as 3GPP GSM, UMTS, HSxPA, LTE, LTE-Advanced) is in the scope of the present document. Link selection within such an integrated framework is handled by the corresponding RAT according to the relevant standards, without implications on the SDR architecture.

4.1.4 Sensing request and delivery of sensing results

Applicable to the terminal and network centric configuration of mobile device scenarios.

The mobile device receives from a network or other mobile devices a request to perform sensing. The mobile device may do the sensing, aggregate the results, and send them back to the requester. The sensing may include RAT specific operations (e.g. finding networks or other mobile devices using specific technologies), feature detection using generic spectrum sensors (e.g. location of specific technologies on certain frequencies), and general spectrum measurements (e.g. detected power levels on certain frequencies).

NOTE: The present document considers only the sensing across distinct technologies that are not designed within an integrated framework (such as 3GPP GSM, UMTS, HSxPA, LTE, LTE-Advanced). Sensing or measurements within such an integrated framework is handled by the corresponding RAT according to the relevant standards, without implications on the SDR architecture.

4.1.5 Change of remote (base station or mobile device) configuration

Applicable to the terminal and network centric configuration of mobile device scenarios.

The base station that the mobile device has a connection to changes its configuration and requires that the mobile device is also reconfigured. This may also happen with a local connection between two mobile devices. The base station provides corresponding reconfiguration information such as the newly used RAT, frequencies, etc., and the mobile device may reconfigure itself in order to maintain the connection.

NOTE: Configuration changes within systems in an integrated framework (such as 3GPP GSM, UMTS, HSxPA, LTE, LTE-Advanced) are not in the scope of the present document. They are handled by the corresponding RATs autonomously according to the relevant standards, and do not have implications on the SDR architecture.

4.1.6 Installing new software components for support of novel standards

Applicable to the addition of new radio software scenario.

New software components to be used by the SDR subsystem are available for the update of the mobile device. These components may be delivered for example using an active RAT. The mobile device (e.g. the SDR subsystem) checks the sanity and compatibility of the new components and may install them to be taken into use. The software components may be new or updated radio applications for the support of novel standards, for instance.

The addition of new software components after the manufacture of a mobile device may have implications on regulatory framework concerning SDR equipment.

4.1.7 Addition of new functionality on top of SDR subsystem

Applicable to the provision of new cognitive features scenario.

New software components are available for the update of the mobile device. These components may be delivered for example using an active RAT. The mobile device checks the sanity and compatibility of the new components and may install them to be taken into use. The software components may be e.g. cognitive control functions for new CR functionality.

As the software components are not used by the SDR subsystem, this use scenario has no impact on the SDR architecture, apart from the delivery of the components using a wireless interface. From the complete mobile device point of view this is important, and should be handled on the higher layers.

4.2 Architecture implications

The functionality outlined above may have the following implications on the mobile device and SDR architecture.

Many of the cross-technology cognitive features can be seen as non-SDR related functionality. For example, initial scanning of available communication partners, possible context information reception using any of the available RATs, and the selection of links are independent of the implementation of the underlying radios. Such intelligence can be built on top of the SDR subsystem.

Any functionality internal to a RAT (individual radio standard or e.g. integrated 3GPP framework) is not in the scope of the present document. Examples of such functionality are searching of beacons or control channels of access points or base stations, message exchange procedures for joining a found network, etc. However, for the cross-technology cognitive features to function, some information from the RATs may be provided. This can include found networks, receive signal strength of these networks, and details of the provided services, for instance. Even if the RATs are not fully configurable by software, providing such information to the layers above can be used to realize a variety of cognitive functionalities.

Finally, as the set of available (i.e. installed) RATs and the cognitive functions may change during the lifetime of the mobile device, the interface between these should be generic. This means, that commonalities between specific RATs are abstracted. Within the present document, these relate to administration functions (i.e. installation and removal of RATs), control (i.e. requests of sensing, establishing connections), and user plane data transfer.

Figure 1: SDR and Cognitive Functionality in reconfigurable radio equipment

Figure 1 shows an example of how the SDR and cognitive functionalities may be split within the reconfigurable radio equipment, in order to enable independent development of both sides.

5 Mobile device SDR operating environment

This clause collects some of the main topics of [i.1], such as the radio computer concept, SDR value network, and the most relevant interfaces.

5.1 Radio computer concept

SDR equipment will operate in the same kinds of networking environments as today's mobile phones, PDAs and laptops. Both licensed and unlicensed frequency bands will remain in use. SDR equipments will be used in user terminals in operators' networks as well as peer equipments in short range, personal and ad hoc networks. Radio and TV broadcasting stations and geopositioning satellites will also be used as distant communication peers of SDR equipments.

Besides existing radio technologies new radio technologies and frequency bands will become available to SDR equipments. Therefore the design of SDR equipment architecture will be prepared for new frequency bands and radio systems – among them especially the ones supporting introduction of cognitive radio systems. More flexible schemes to use available radio frequencies will also emerge by introduction of spectrum sensing techniques, distribution of cognitive control information and use of commonly agreed spectrum etiquettes. From the SDR equipment architecture point of view both network-centric control schemes and autonomously operating mobile devices are equally valid in such future spectrum utilization cases.

Instead of engineering radios as embedded systems on RFICs, special-purpose digital signal processors and ASIC accelerators, future software defined multi-radio equipment may be seen as a computer where individual radio applications are engineered as software entities to run on more general-purpose computing elements. Such a **radio computer** is capable to run multiple radios simultaneously and can change this set of radios by loading new radio application software even at run-time. All radio applications exhibit a common behaviour from the radio computer point of view.

In order to share the available computing, memory, communications and RF resources the radio computer has a radio operating system, just like desktop computers have their operating system. Such a radio operating system supports coexistence of multiple radios even if they are operating on same or adjacent frequency bands. Radio operating system also provides run-time reconfiguration by installing, loading and activating new radio applications.

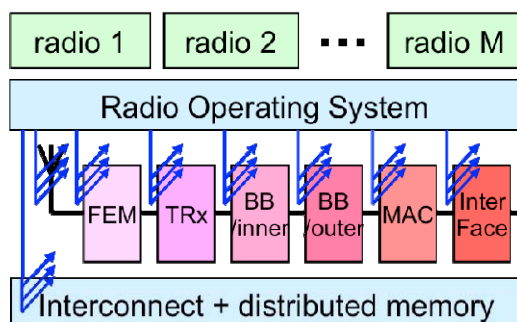

Figure 2: Radio computer concept

This parallelism to desktop computing leads to architecting the functionalities of a multiradio equipment as three horizontal layers: physical radio computing platform, operating system and radio applications as shown in Figure 2.

The decoupling of the radio applications from the physical hardware platform and the user entities requires the definition of four generalized interfaces. The first important system-wide interface needs to be specified at the boundary between the common radio computer platform and the specific radio applications. This **Unified Radio Application Interface** (URAI) is used to adapt and align all kinds of radio applications under the common reconfiguration, multiradio execution and resource sharing framework of the SDR reference architecture.

The second key interface relates to the independent and uniform production of radio applications as software entities. This can be achieved by introducing as part of the architecture a **Radio Programming Interface** (RPI). This is both a radio software development time concept as well as a run-time interface between radio software entities and the radio computer platform. This interface needs to include a uniform radio programming model that combines required run-time dynamism with real-time guarantees and efficiency. The programming model needs to be platform neutral and allow multiple radio compilers to be used for generating run-time radio packages for different platforms from the same source program. Additional aspects to be taken into account in the radio programming interface are virtualization of hardware peripherals of the radio computer such as reconfigurable RF devices.

The third common interface may be defined due to the foundational role of RF circuitry in any radio equipment. We anticipate the emergence of a more generic **Reconfigurable RF Interface** (RFFI), which will support multiple radio applications and may even support sharing of the same circuitry among simultaneously active radio applications with similar enough RF properties.

Finally, because the software defined radio subsystem is also decoupled from the higher layer network protocol stacks (e.g. TCP/IP) and associated cognitive entities, the SDR equipment provide a service interface to its user entities. Such a **Multiradio Interface** (MURI) provides a uniform way to access all radio applications in the SDR equipment.

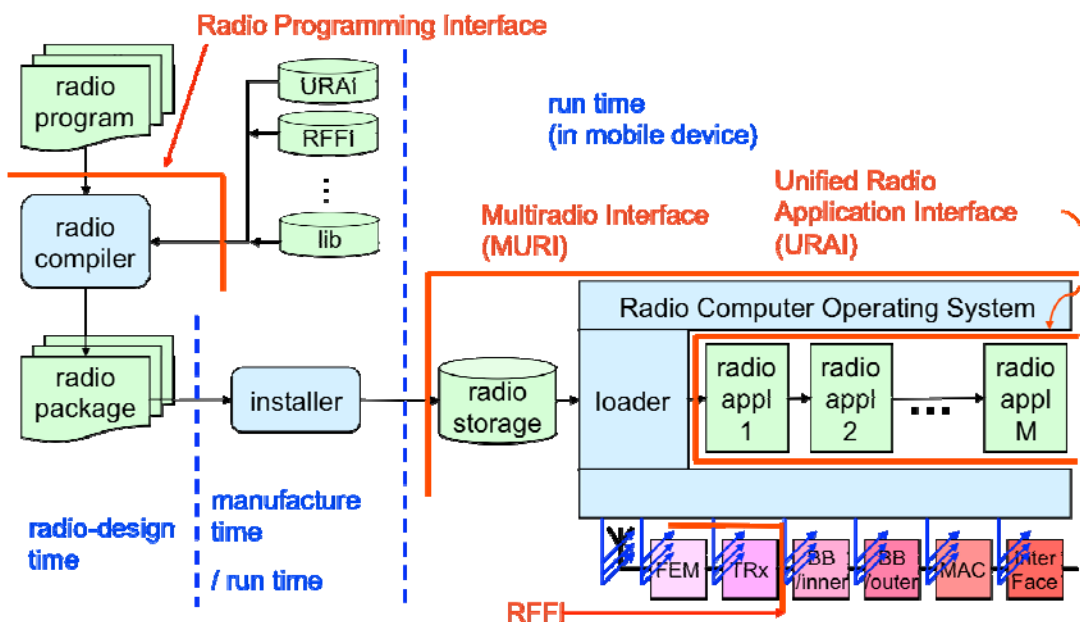

Figure 3: Compile-time and run-time functions of a radio computer

Figure 3 illustrates a scenario, where a **radio compiler** is employed to support this kind of programming model. Radio programs are built into radio packages in compile-time. Radio package contains not only the binary code of the radio program components but also metadata about the radio system. Included into such metadata descriptions are the structure of the radio application program, radio system parameters (e.g. modes or frequency bands of multi-mode or multi-band radio systems) and also the pre-calculated run-time resource requirements, which are expressed as resource budgets.

During run-time (or if so selected already at manufacturing time) the loader component of the radio operating system will install and load radio packages into the execution environment of the radio computer. Binary code is loaded into memories available to processing elements. Radio applications are initialized with the provided radio system parameters and resource budget data is made available to the resource manager components of the radio operating system.

5.2 SDR value network

Figure 4 below outlines potential business relationships between different mobile device SDR stakeholders.

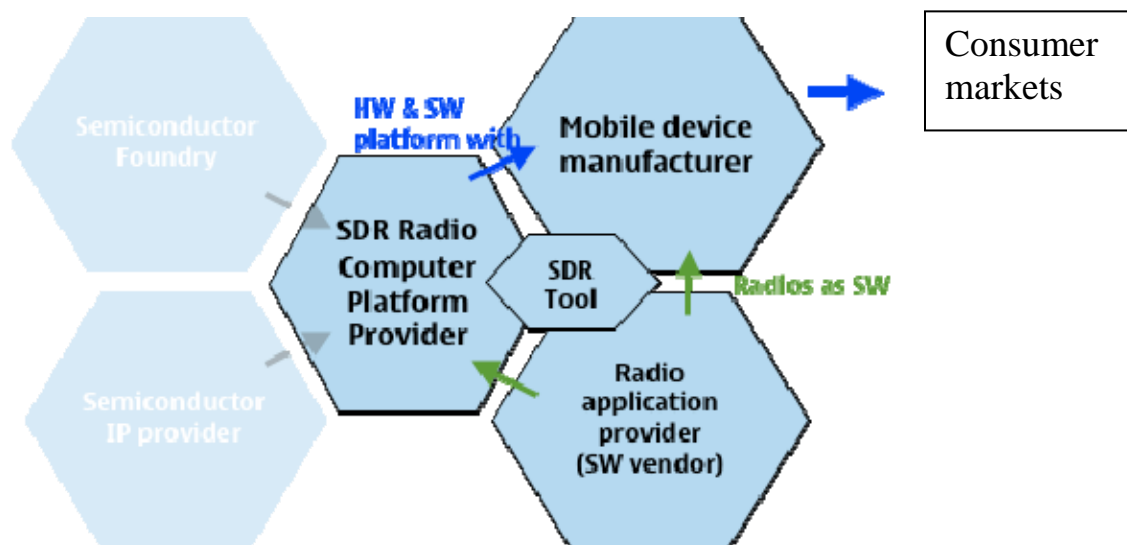

Figure 4: Future SDR value network

With the introduction of the SDR technology the radio chipset vendors will become responsible for integration of complete radio computers. They may use separate manufacturing companies (semiconductor foundries) and integrate also IP blocks from other semiconductor vendors e.g. outer modem HW accelerators. Such radio computers, which may include some built-in radio applications, are provided as radio platforms to mobile device manufacturers. Mobile device manufacturers develop their consumer products, like mobile phones, multimedia computers and PDA devices, which use the radio computers as subsystems for communications purposes. Mobile device manufacturer may also choose to implement itself some radio applications into the radio computer platform. While radios continue to be used for multiple different purposes and new radio technologies continue to emerge development of radio applications as software entities may become a business of own. Such radio application providers may develop and market their radio applications to multiple radio computer vendors and mobile device manufacturers. This kind of value network may also allow some software companies to become radio software tool vendors having multiple radio developer companies as their customers.

To have potential for wide adoption, the SDR architecture interface definitions should fall at these stakeholder boundaries.

5.3 Radio computer capabilities

The SDR platform is designed as multiradio computer platform, which may be composed of one or more general purpose control processor(s) and of one or more specialized co-processors (e.g. digital signal processor clusters, vector processors etc). This kind of heterogeneous multi-processor architecture operates under tight real-time constraints [in μ sec range] and is bound by a tight power budget. Dynamic reconfiguration of the hardware platform also needs to be supported by the architecture. How to provide secure execution environment for all radio applications running on a common radio computer platform is also an important design criteria.

Specifically, three types of multiradio SDR capability requirements have been identified in [1.1], each of which may have impact on the multiradio interface definition:

Multiradio configuration capability: SDR equipment in mobile device is expected to install, load and activate a radio application while running a set of radio systems already. Correspondingly it allows active radio systems to become deactivated, unloaded and uninstalled.

Multiradio operation capability: SDR equipment in mobile device is expected to execute number of radio systems simultaneously by taking into account temporal coexistence rules designed for their common operation to mitigate inter-radio interference.

Multiradio resource sharing capability: SDR equipment in mobile device is expected to execute number of radio systems simultaneously by sharing computation, memory, communications and RF circuitry resources available on the radio computer platform by using appropriate resource allocation, binding and scheduling mechanisms.

5.4 Radio computer deployment scenarios

Being the interface towards SDR user entities, the multiradio interface definition should cover usage in various steps of SDR platform advances. A phased approach is described, where each phase introduces new elements to the multiradio computer. These elements are related to resource sharing capability between the concurrently active radio applications.

5.4.1 Scenario 1: Radio access technologies are legacy implementations

In this scenario at least some of the radios are implemented with non-SDR technology, e.g. with dedicated ASICs, and are resource-wise independent of each other. The multiradio interface collects the control and user plane functionalities of the diverse radios in a uniform manner, allowing easier development of architecturally coherent connectivity and mobility management features. Simple cognitive radio functionality may be supported through radio parameter management to the extent, which the radio implementations allow.

5.4.2 Scenario 2: Radio applications use pre-defined fixed resources

In this scenario, no dynamic resource management is available in the multiradio computer. The radio applications come from a single source, typically the mobile device vendor or SDR chipset manufacturer. The application vendor also provides a list of possible radio combinations that may run on the platform concurrently; such a list could for example be "WiFi runs in parallel to GSM". The resources used by the applications running in parallel are fixed; the resource allocation may be done during compile time, when the radio application package is created by the vendor. The multiradio computer resource manager only does fixed resource assignment, when the application is placed into execution. If dynamic resource management is applied within the fixed resource assignment, it is hard-coded in the application itself.

If a new radio application is installed, a new list of possible parallel radio combinations is also provided.

5.4.3 Scenario 3: Radio applications have fixed resource requirements

Once the amount of radio applications become available, the list of possible parallel radio combinations may become unwieldy. In this scenario, a resource budget is defined for each radio application. This budget contains a fixed resource measure that represents the worst-case resource usage of the application, generated at compile time. If an application is being started, the resource manager checks its resource budget and the sum of all resource budgets of already running applications, and admits the new application only if the resources can still be guaranteed for all running applications.

Because of more flexible resource allocation, in general the same platform can run more concurrent radio applications than what is possible in scenario 1. The penalty is that applications may not have enough resources to get into execution, and this is not known until an admission check is done.

5.4.4 Scenario 4: Radio applications have dynamic resource requirements

This scenario assumes a similar resource manager as in scenario 2, but in addition the radio applications have now varying resource demands based on their current type of activity. Applications have separate operational states for different types of activity, and a resource budget is assigned to each operational state. The resource manager does admission control and resource reservation when applications are being started, but also when they request to transition into a new operational state with different resource demand.

5.4.5 Scenario 5: Radio applications come from third-party vendors

In this scenario, the methods of radio programming and the tools to support this have become sufficiently standard so that third-party vendors may create radio applications and port them to different platforms with relative ease.

6 SDR mobile device reference architecture overview

The functional architecture of a multiradio computer device is illustrated in Figure 5 [i.1]. It is a platform neutral, radio system neutral, abstract architecture. The key components are SDR control framework, unified radio applications, and the interfaces to these; in this clause these components are described on a general level.

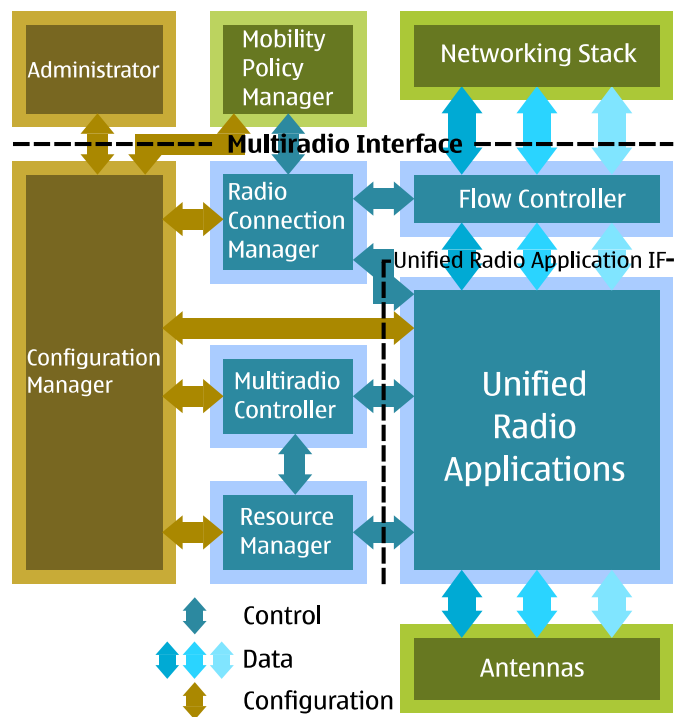

Figure 5: Functional architecture of SDR equipment

Instead of engineering radios as embedded systems on dedicated ASIC circuitry, future software defined multiradio equipment may be seen as a computer where individual radio applications are engineered as software entities that run on more general purpose computing elements. Such a radio computer concept is the basis for the functional architecture. Specific requirements are for example that radio applications may be installed, loaded, and activated while running a set of radio applications already, and that platform resources may be shared between the concurrently active radio applications. A more detailed list of requirements may be found in [i.1].

6.1 SDR control framework

The common SDR control framework provides a generic platform for the radio applications to run on, and a uniform way of accessing the functionality of the radio computer and the individual radio applications. The control framework, which represents functionalities provided by the multiradio computer operating system, is itself radio system neutral, but requires all radio applications to be subject to the common reconfiguration, multiradio execution and resource sharing scheme. Since all radio applications exhibit a common behaviour from the radio computer perspective, they are called Unified Radio Applications (URA), and they interface to the SDR control framework with the Unified Radio Application Interface (URAI).

Towards the user applications the radio computer presents the Multiradio Interface (MURI), which is also the main topic of the present document. All services of the multiradio computer to its user applications are provided at this interface. These include connectivity and data transfer, but also other kind of services like positioning and broadcasting services. The multiradio management, control, and user planes are represented by Administrator, Mobility Policy Manager, and Networking Stack users respectively.

The components of the SDR control framework have different responsibilities as follows:

- **Configuration Manager (CM):** installation/uninstallation and loading/unloading of radio applications into multiradio computer as well as management of and access to the radio parameters of those radio applications.
- **Radio Connection Manager (RCM):** activation/deactivation of radio applications according to user requests, and overall management of user data flows, which can also be switched from one radio application to another.
- **Flow Controller (FC):** sending and receiving of user data packets and controlling the flow.
- **Multiradio Controller (MRC):** scheduling the requests on spectrum resources issued by concurrently executing radio applications in order to detect in advance the interoperability problems between them.
- **Resource Manager (RM):** management of multiradio computer resources in order to share them among simultaneously active radio applications, while guaranteeing their real-time requirements.

6.2 Unified radio applications (URA)

The SDR control framework both provides its common services to all radio applications as well as requires every radio application to provide a minimal set of common behaviour in order to be manageable as an application of the multiradio computer. Such radio applications comply with the unified radio application concept.

Following the multiradio computer concept, the SDR control framework allows installation and loading of radio applications during run-time. A set of radio applications may be pre-installed into the multiradio computer, and new ones may be brought in by using the administrator services of the multiradio computer. We describe the life cycle of a radio application inside the multiradio computer by using four distinct **administrative states**, which differ by their use of the shared platform resources:

- not installed
- installed
- loaded
- active

A not installed radio application is unknown to the multiradio computer. In the installed state, the multiradio computer has stored a copy of the radio application package, which includes executable code for radio application and the metadata describing its resource needs and parameters. It may be stored as compressed in mass storage, for instance, for minimal memory footprint. A loaded radio application is available to the users of radio computer, i.e. it can be seen at the multiradio interface by the Mobility Policy Manager, but is not yet in execution. Once a copy of the radio application is in execution, it is considered to be in the active state, and is actively using the resources of the multiradio computer.

From the resource use point of view, the active administrative state is the most interesting. Inside the active state a set of **operational states** may be defined for a radio application to describe different resource requirements. For example, an IEEE 802.11 [i.3] WLAN station that is in the power-saving mode only needs to process beacon frames sent by the access point, and has no need for any transmitter resources, leaving them available to other radio systems. If the access point indicates buffered frames for the station, or the station itself has frames to transmit, transition to normal operational state occurs.

It is the sole responsibility of the radio application designer to decide, how many and which operational states the radio application will have. By dividing the life-time of the radio application into various operational states the designer can facilitate more efficient resource sharing. Inside an operational state, the radio application is allowed to operate freely within the given limits of the granted resource budget. Transitions between operational states are triggered by the user or an external entity (e.g. radio network), and are requested from the Resource Manager, which keeps track of resource allocations. No real-time guarantees are given for serving these requests, and the radio application will have to accept also denials of state transition requests due to resource limitations. In those cases, the radio application may propagate the denial to the multiradio interface so that the higher-level control elements can take the necessary actions (e.g. deactivate lower priority radios thereby freeing resources). The SDR control framework guarantees resources for the granted operational states of the active radio applications.

The concept of unified radio application may refer to already standardized radios or to new radios, which are likely to emerge e.g. from the cognitive radio development. New radios may become designed in such a way that they are compatible with the URA concept. For legacy radios an adaptation is typically necessary in order to make them follow the URA behaviour. Such an adaptation will not change the already standardized behaviour of a radio device as observed by its peer radio devices. Examples of legacy radios, which may be regarded as URAs are:

- Cellular multimode GSM/WCDMA/LTE radio with standardized intersystem handovers.
- Combined WLAN 802.11b/g + Bluetooth radio with standardized coexistence on 2,4 GHz band.
- Multimode Digital Broadcast radios.
- GPS/Galileo radio for geopositioning.

6.3 Key interfaces

The SDR control framework provides a radio access technology independent platform to run the radio applications on. This creates the need to specify generic interfaces at the boundaries where radio access technology independent and specific parts interact:

- Interface between the user applications and the multiradio computer (Multiradio Interface, MURI).
- Interface between the radio applications and the SDR control framework (Unified Radio Application Interface, URAI).
- Radio Programming Interface (RPI) including programming models for signal processing, and primitives to access the services of the radio operating system.
- Interface to the reconfigurable RF transceiver.

The first two are described with more detail in clauses 6.3.1 and 6.3.2.

6.3.1 Multiradio interface (MURI)

The services of the multiradio computer are available to the Administrator, Mobility Policy Manager, and Networking Stack users at the Multiradio Interface. It provides a uniform way to access all radio applications in the SDR equipment. Three different kinds of services can be distinguished based on the role of the user entity.

Administration services are used by some device configuration application (the Administrator user) to install and load new radio systems into the multiradio computer. Installation and loading may take place both at device start-up time to set up radios for constant use as well as during run-time, whenever reconfiguration of available set of radios is needed. Multiradio interface does not make any assumption on how and when the mobile device will detect the need of reconfiguration.

The user of *access control services* is modelled as the Mobility Policy Manager entity, which maintains the user policies and preferences on different radio access technologies and makes the selection between them. Modelling of such preferences and selection algorithms is outside the scope of the present document; however, the support to get information and make these selections should be present at the MURI. The preferences themselves may originate either locally from applications or end user settings as well as in a distributed manner from network operator or from a cognitive radio management scheme.

Data flow services are typically used by the networking stack of the mobile device, e.g. the TCP/IP stack. Therefore data flow services represent the set of (logical) link layer services, which are provided in a uniform manner regardless of which radio application is actually used to maintain the link.

6.3.2 Unified Radio Application Interface (URAI)

The purpose of the Unified Radio Application Interface is to harmonize the behaviour of radio applications towards the radio computer operating system. To achieve this, all radio applications will access and provide a well-defined set of services specified in the Unified Radio Application Interface. They gain access to the shared platform resources and the radio spectrum only by using those URAI services.

URAI is a bidirectional service interface, where both provided and used services are visible.

The services provided by unified radio applications relate to activation and deactivation, peer equipment discovery and maintenance of communication over user data flows. Even though mapping of specific radio functionality to the URAI services may not always be straightforward, the benefit is that all radios can be used in the same manner.

The services provided by the SDR control framework to the unified radio applications include resource management and scheduling of spectrum access requests.

7 Multiradio interface design goals

The design goals that can be derived from the previous clauses are recapped here.

Modern design principles need to be followed in the multiradio interface definition. This may mean model driven and component-based design practices in order to end up into a modular architecture that can be expanded and revised. This also helps to support integration of radio application software from different providers. Also portability of radio applications from one SDR platform to another is to be seen as important design criteria.

The multiradio interface definition should support multiple radio technologies, including existing cellular access and non-cellular radio technologies as well as new ones which are likely to emerge with the introduction of cognitive radio systems. The radio applications in the SDR equipment will continue to conform to their specific radio interface specifications and standards. Both connectivity radios (for user data transfer) and other types of radios, such as digital media broadcasting, geopositioning and wireless sensing radios need to be supported by the common SDR reference architecture.

The use of legacy radio implementations needs to be supported without extensive modifications to existing control software. The multiradio interface should be largely independent of the extensiveness of the underlying SDR control framework implementation. In the simplest form the multiradio interface implementation is a wrapper around the existing radio interfaces. In more advanced implementations there is also the full-fledged SDR control framework allowing more intelligent resource sharing and interoperability schemes as well as optimization of the used the radio applications.

Cognitive radio functionality on top of the radio computer should be fully supported by the multiradio interface. The SDR platform provides mechanisms such as environment measuring and parameter management that can be basis for cognitive radio system functionality (e.g. radio access technology and frequency band selection). Both network centric and mobile device centric reconfiguration of the radios should be supported.

Finally, the multiradio interface should include radio equipment testing capability. Besides the architectural and technological requirements discussed above the SDR equipments will bring new kinds of usage scenarios, which are likely to require additional mechanisms to become accepted in mass markets. The conformance of all radios and their combinations on the same platform will still fulfil the EMC and other product safety regulations. The conformance testing of SDR equipment may require additional measures, which need to be investigated also. The introduction of computerized SDR equipment is bringing programmability of mobile devices into a level, which needs to be accompanied with appropriate mechanisms to ensure authentication and secure operation of installed radio applications on every SDR platform.

8 Multiradio interface concept definitions

This clause collects the definitions of terms that are used in the mobile device SDR reference architecture and the multiradio interface.

Activation of a *radio application* means it is placed into execution in the *multiradio computer*, to do its functionality as specified in the radio system specifications. *Users* may only request to use the services of active *radio applications*. An active *radio application* is consuming computation, memory, communications, and RF circuitry *resources* according to its needs in the *operational state* it is in. If **deactivated**, a *radio application* stops executing its behaviour and resets to its initial state, but is nevertheless readily available in the *multiradio computer*.

Administrative states describe the life-cycle of a *radio application* in the *multiradio computer*. Four distinct administrative states have been identified. A not installed *radio application* is unknown to the *multiradio computer*. An installed *radio application* is inside the *multiradio computer* boundaries, for instance stored in mass storage in a compressed format. A loaded (or instantiated) *radio application* is available for the *user* for *activation* and its *parameters* may be managed, but is not yet executing. An active *radio application* is executing in the *multiradio computer*, doing its functionality according to the radio system specifications, and consuming computation, memory, communications and RF circuitry *resources* according to its needs in the *operational state* it is in.

Association is a logical communication link to a *peer communication equipment*. In communications radio systems (e.g. cellular, local area) it means a two-directional link where both sides know the other is there. In broadcast radio systems an association may be defined as the mobile device tuning to receive a certain channel, station, or equivalent. Typically, some control signalling is necessary to maintain the association. No user plane data transfer may occur with only an association present, but a *flow* may be established into an association for this purpose. The maximum amount of concurrent associations for a *radio application* is typically limited by the radio system specifications, for example it is unlikely that a cellular mobile device may have associations to the GGSNs of two or more operators at the same time.

Flow (data flow) is a user plane data link that is attached to an *association*. Examples are circuit switched phone call, voice over IP call, reception of an SMS, sending of a contact card, PDP context for internet access, demultiplexing a TV channel from a channel multiplex, calculation of position coordinates from geopositioning satellite signals, etc. A flow may only be established when there is already an *association* present. Typically, both sides of the *association* may initiate a flow, and both sides may terminate it. The maximum amount of flows in an *association* may be limited by the radio system specifications. It may be possible to move a flow from one *association* to another, even across *radio applications*.

Installing means that a *user* brings a (potentially previously unknown) *radio application package* into the *multiradio computer*. Semantically this means that the *multiradio computer* is aware of the *radio application*. Installation may have several steps for example related to authentication, verification, and compatibility checks. The *radio application package* may be stored in mass storage in compressed format, for instance. **Uninstalling** a *radio application package* means that the *multiradio computer* is no longer aware of it.

Loading or **instantiation** may only be done on *installed radio applications*. Semantically this means that the loaded *radio application instance* is available for the *user* for *activation* and its *parameters* may be managed, but the *application* is not yet executing. **Unloading** a *radio application instance* means it cannot be *activated* before it has been *instantiated* again; this may be used to save *resources*, for instance.

Multiradio computer is the part of the connectivity system under the multiradio interface, containing the SDR control framework, and a number of unified radio applications. The SDR control framework can be seen as the SDR hardware platform plus the radio operating system providing the execution environment for the *radio applications*. Together these parts provide the services of the multiradio interface.

Operational states are used to describe *resource* need of a *radio application* when it is in the *active administrative state*. Technically, a *resource* need or description is attached to each operational state, which themselves describe more the temporal behaviour of the *radio application* when in that state. The *active administrative state* may be divided into one or more operational states, depending on if distinctive behaviour is found in the radio system (e.g. power-save vs. telephone call), and if these behaviour patterns have different enough *resource* needs. The definition of the operational states for a *radio application* targeted for a specific *multiradio computer* platform is the responsibility of the radio application designer.

Peer (communication) equipment is any communication counterpart of a SDR equipment. It can be reached by establishing a (logical) communications link (i.e. an *association*) between the SDR equipment and peer equipment. Examples of peer equipment are WLAN access points, IP access nodes (GGSN, etc.) in cellular networks, Bluetooth headsets, digital radio and TV broadcasting stations, GPS satellites, etc.

Sometimes it may be necessary to distinguish between the peer radio equipment (e.g. a cellular base station) and the peer communication equipment (IP access node or GGSN in cellular network). Otherwise in the present document peer equipment means always a peer communication equipment. As illustrated in Figure 6 peer radio equipment are connected with radio links and peer communication equipment are connected over (logical) communications links.

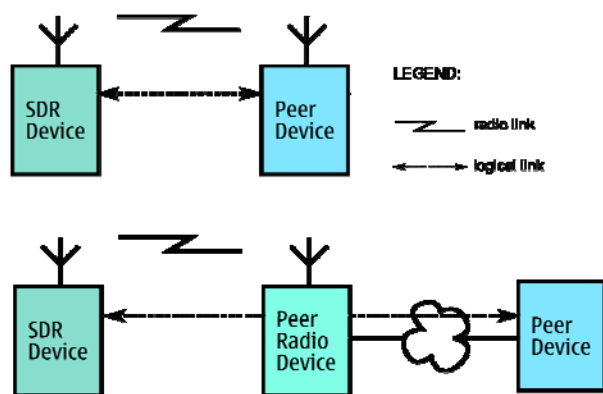

Figure 6: Peer communication and radio equipment

Radio application means software-based implementation of any specific radio access technology. A *multiradio computer* is able to run unified radio applications (URA), which additionally to the radio system specifications comply with the unified radio application interface (URAI).

Radio application package contains everything needed by the *multiradio computer* to run the URA. This includes the executable components, *resource* needs, manageable *radio parameters*, plus any metadata (information needed e.g. for installation, authentication, etc.). Separate packages of the same *radio application* may be compiled for different hardware platforms. Variants of a *radio application* (e.g. variants of IEEE 802.11 [i.3], 3GPP standards, etc.) may be included in the same package, or split into separate packages.

Radio instance is an *activated radio application*, extracted from the *radio application package* and put into execution by the *multiradio computer*, or readily available for execution. The *radio parameters* for the instance are available to be modified by the *user*. It may be possible to *instantiate* the same *radio application* multiple times, with separate parameter sets and independent operation (within limits of shared *resources*).

Radio parameters that the *radio application* exposes to the *user* may be used to configure its behaviour. These can be defined by the application designer. Example parameters may be for instance allowed frequency bands or channels, used variants (see *radio application package*), authentication tokens, or similar.

Resources are provided by the *multiradio computer*, to be used by the *radio applications* when they are *active*. *Radio applications* provide their resource needs (e.g. using *operational states*) so that the *multiradio computer* may judge whether these resources are available, in order to ensure non-conflicting operation with other *applications*. Resources may or may not be shared in the *multiradio computer*.

User is an abstract representation of any entity issuing command requests (i.e. using the services) to the *multiradio computer*. Three types of users are distinguished based on the type of services used: administrator for multiradio management plane, mobility policy manager for control plane, and networking stack for user plane.

9 Information model

This clause describes the information that is exchanged at the multiradio interface. The information is organized in a UML model. This approach enables formal definition of the information on a rather abstract level, and the extension and specialization of the desired elements later on.

In general, further specialization of the information elements defined in the model may be done towards three goals:

- 1) Radio access technology specific definitions (e.g. parameters and behaviour that is specific to a radio access technology).
- 2) SDR platform specific definitions (e.g. taking into account hardware and software capabilities of the platform such as resource sharing).
- 3) Generalizations of 1) and 2), if commonalities are found, towards the SDR reference architecture.

9.1 Radio application package

The static content of the radio application package is described here. There exist separate packages for each of the different URAs that the SDR mobile device handles. A radio application package includes everything that is needed for the URA to execute and operate on a certain platform. It is not specified how multiple separate URAs can share parts of the package in order to save e.g. memory.

Figure 7: Definition of installed radio application packages within the multiradio computer

The RadioApplicationPackage can be decomposed into smaller parts, as shown in Figure 8. The Capabilities class describes how the radio application is able to behave, and what parts (parameters) of it can be managed. The ExecutableComponents contain the actual run-time components that execute on the hardware/software platform. There may be metadata components to describe the content for the multiradio computer.

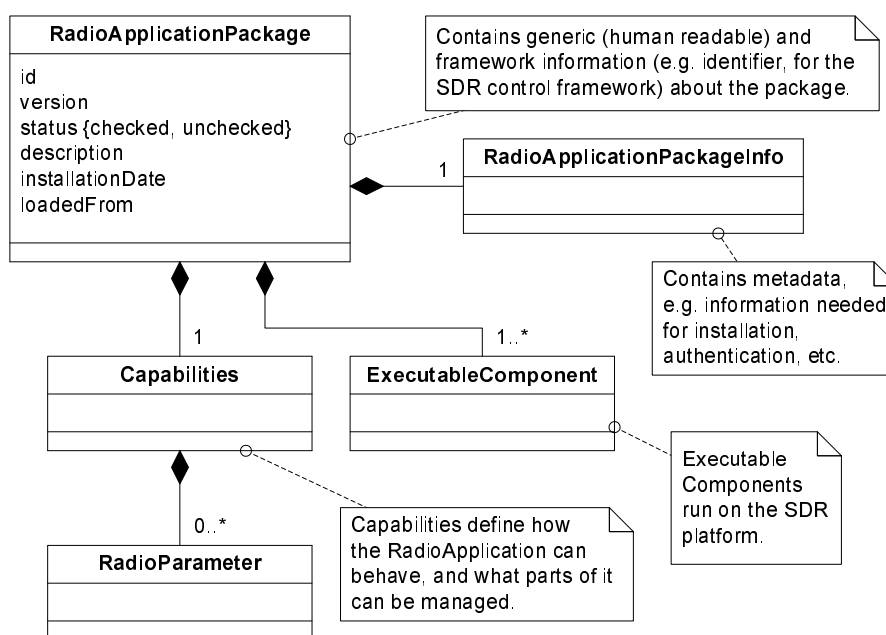

Figure 8: Decomposition of the radio application package

9.1.1 Capabilities

The definition of Capabilities and RadioParameters is radio access technology specific. Capabilities are an abstract representation of the highly specific RadioParameters, for example a radio application might be capable of reporting received signal strength, or using a certain frequency band or data rate. RadioParameters can be the specific values of the capabilities.

9.1.2 Executable components

Further decomposition of the ExecutableComponent class may be done towards type of resources they are using. Platform component denotes a resource, which may be for example a processors, hardware accelerators, etc. Further information may be attached for example to describe the resource utilization rate, communication bandwidth, memory footprint, etc.

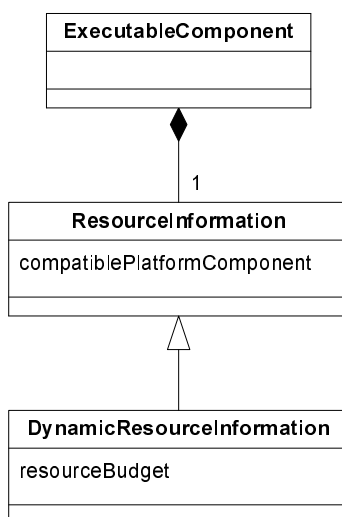

Figure 9: Specialization of executable components

9.2 Radio application instances

An installed radio application package can be instantiated, to create the radio application to be later executed. The same package may potentially be instantiated more than once, and the application instances may be deleted if not needed.

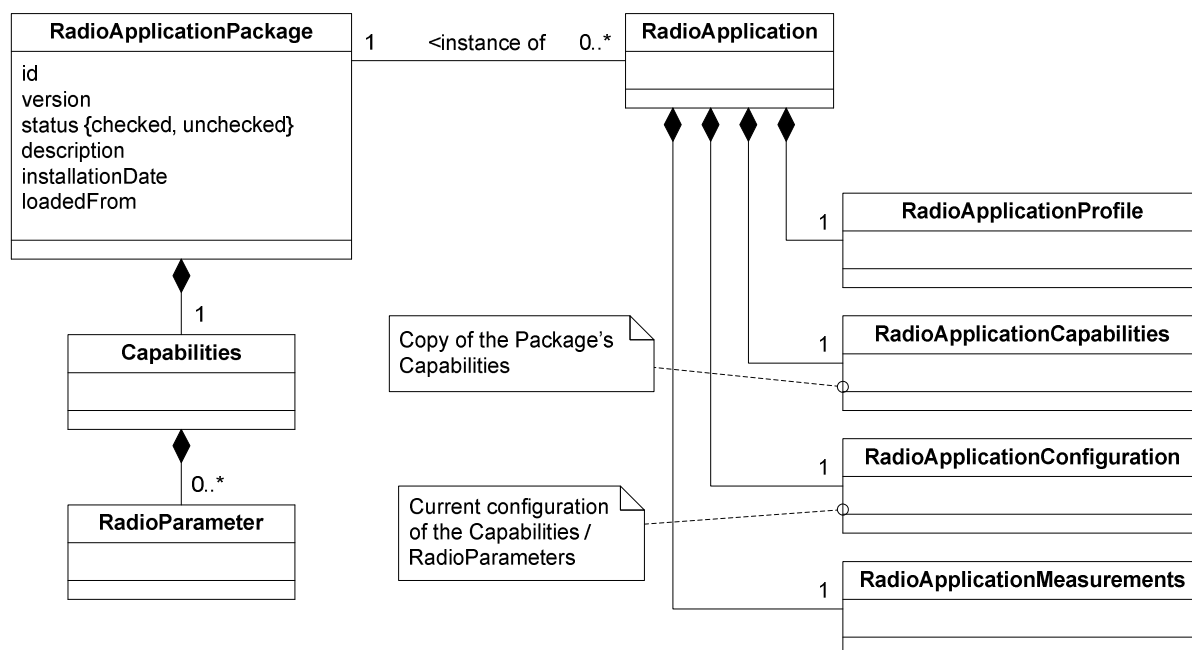

Figure 10: Definition of instantiated radio applications

The instantiation of a radio application creates a set of information elements that can be managed before placing the application into execution, and also during execution. The RadioApplicationCapabilities is a copy of the Capabilities of the corresponding RadioApplicationPackage; the Capabilities of each instance may be limited from the complete set. The RadioApplicationConfiguration on the other hand is the current configuration of the instances' Capabilities.

9.3 Measurement information from radio applications

The information that is available for the user during run-time is described here.

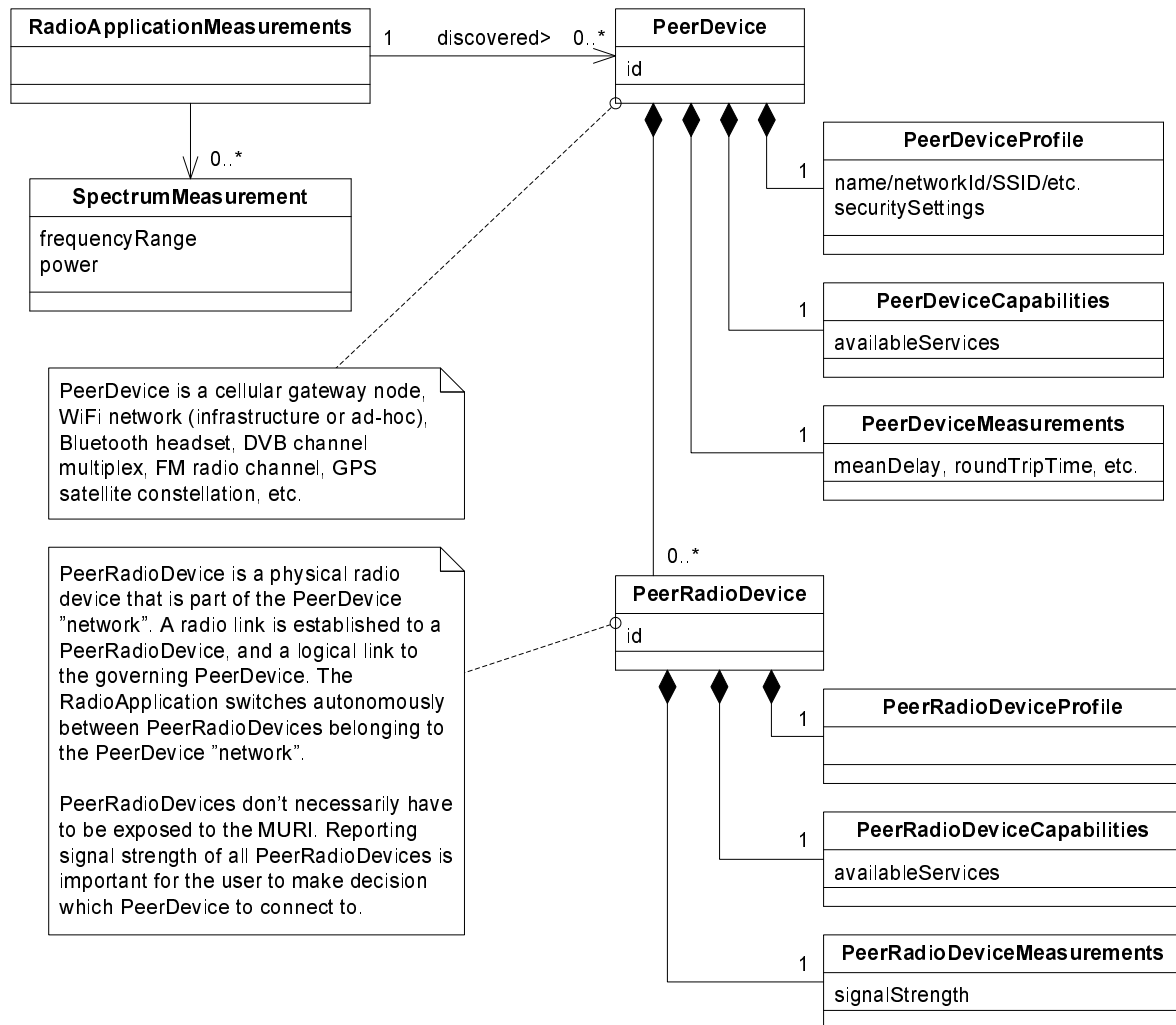

Figure 11: Definition of measurement information

The measurement information includes discovered Peer Devices and measurements of spectrum. For each Peer Device, there may be reported a profile (with name, settings, etc.), capabilities (like available services), and specific measurements attached to that PeerDevice. Further, each PeerDevice has a number of PeerRadioDevices that may also each contain a profile, capabilities, and measurements.

9.4 Connectivity elements

This clause describes the run-time aspects of an active radio application.

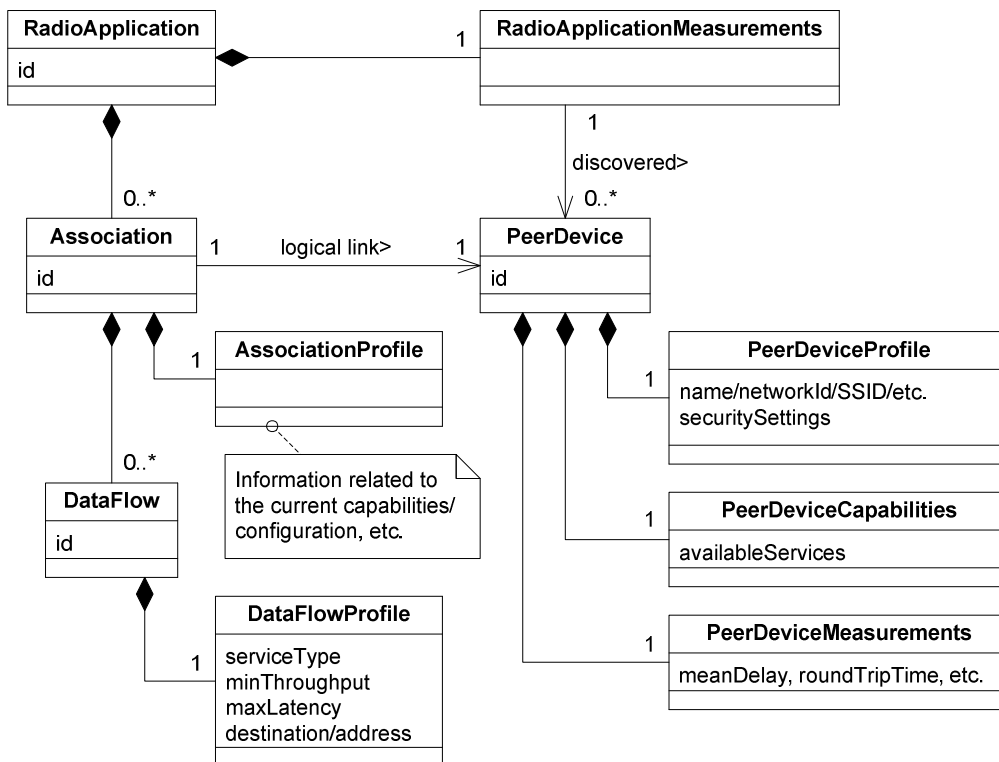

Figure 12: Definition of connectivity elements

Each `RadioApplication` may have a number of `Associations` which represent logical links to `PeerDevices`. The creation of an `Association` may be originated by the mobile device or the `PeerDevice`. Capabilities and other information of the `PeerDevice` are available through the `RadioApplicationMeasurements`, but the `Association` itself may for instance only use part of the possible `Capabilities`; for this reason there is an associated `Profile` for each `Association`.

`DataFlows` are established to carry user data to and from the `PeerDevice`. For this reason, `DataFlows` are always attached to an `Association`, and may also be initiated by the mobile device or the `PeerDevice`. There is also a `Profile` for the `DataFlows`.

The `Profiles` for `Associations` and `DataFlows` may for instance inform the multiradio computer about the requirements for the communication link. With a simple "service type" parameter it is possible to distinguish several traffic patterns, like streaming delay tolerant data (e.g. web video streaming), streaming delay sensitive data (e.g. phone call, video call), priority best effort traffic (e.g. mobile gaming, foreground web browsing), and background traffic (e.g. email sync). With identifiers for each flow it is possible to distinguish between different types of traffic, to better support quality of service. All this information can then be used when optimizing the performance of the radio access technologies.

10 Service description

This clause describes the multiradio interface services that are visible to the multiradio computer users, i.e. Administrator, Mobility Policy Manager, and Networking Stack. The services are described using signalling diagrams, which show the signal order and possible responses. The associated information in the signal parameters is not given, but each service accesses, modifies, or otherwise relates to information elements described in clause 8.

The multiradio computer's services are shown in Figure 13.

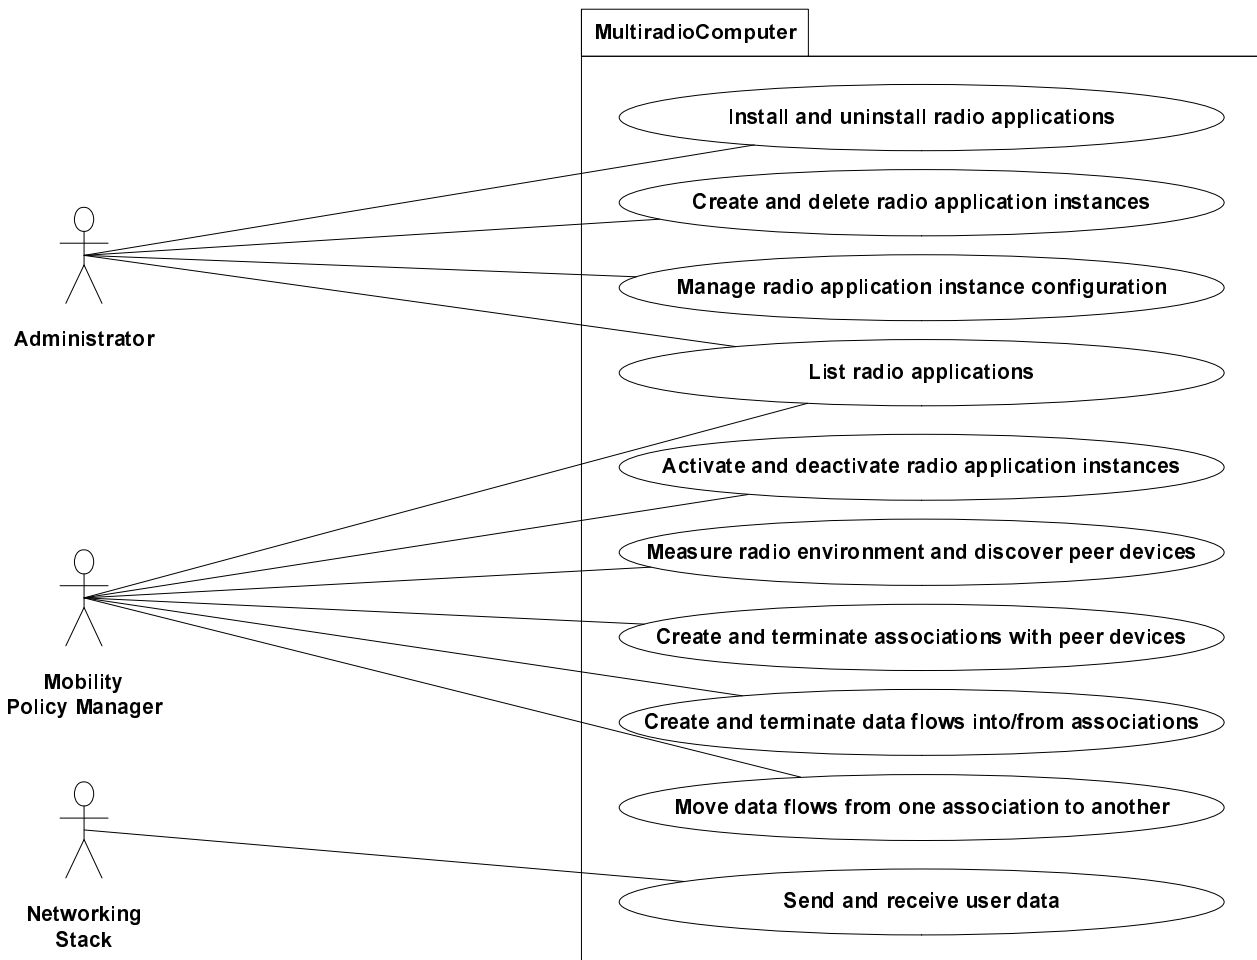

Figure 13: Services of the multiradio computer

Within the present document, the following definitions apply:

- Signals that initiate some functionality at the service provider are requests (Req); the service provider responds by confirmation (Cnf) or fail confirmation (FailCnf) signals.
- Signals that are initiated by the service provider are indications (Ind); if needed, the service user reacts by response (Rsp) or fail response (FailRsp) signals.

The roles of service user and provider are clear in the case of the multiradio interface – all services are provided by the multiradio computer. This may not be as clear if looking at the reference architecture's unified radio application interface, which is bidirectional. It is indicated wherever certain functionality, for example generation or handling of identifiers, is required of the service user.

10.1 Administrative services

Radio applications, which have been installed in the multiradio computer, are available for use. The administrative services allow installation and uninstallation of radio application packages. Further, installed radio applications can be instantiated (for activation) and instances deleted (to save resources). These installation and instantiation operations may take place at device start-up time or during run-time whenever reconfiguration of available set of radios is needed. Capabilities of the radio application instances may be managed, whether they are active or not. A list of radio applications inside the multiradio computer is available.

The Configuration Manager of the reference architecture provides these administrative services.

10.1.1 Install radio application

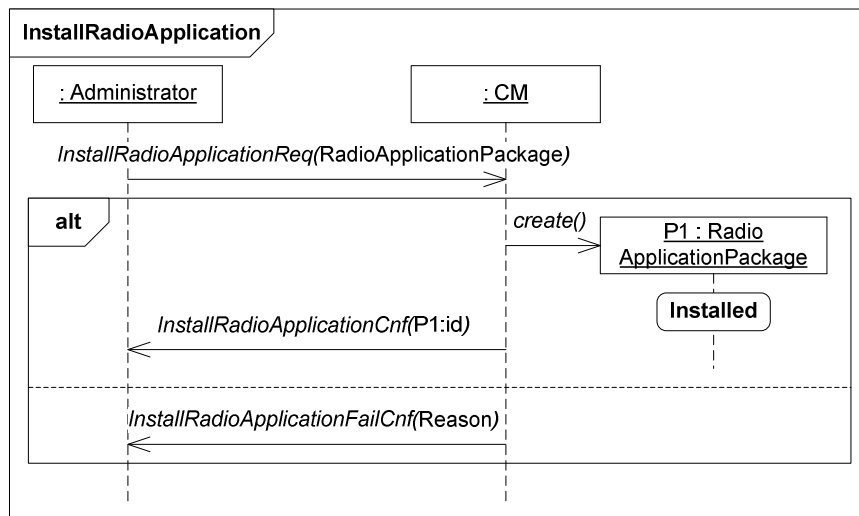

Figure 14: Install radio application signalling diagram

The radio application installation procedure goes as follows:

- The Administrator user gives the radio application package to the Configuration Manager using *InstallRadioApplicationReq*.
- CM evaluates the radio application package authentication and compatibility, and performs installation if evaluation checks succeed.
- If the application is successfully installed, CM replies with *InstallRadioApplicationCnf* including a handle (id) to the installed radio application. Otherwise *InstallRadioApplicationFailCnf* is sent with appropriate reason why the installation failed.

10.1.2 Uninstall radio application

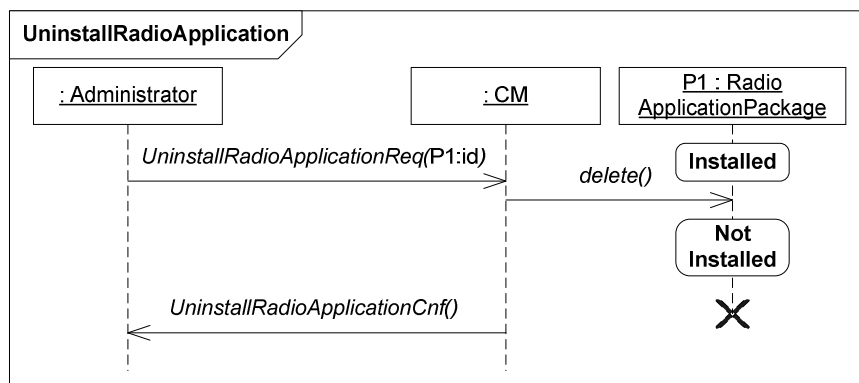

Figure 15: Uninstall radio application signalling diagram

The radio application uninstalling procedure goes as follows:

- The Administrator user sends *UninstallRadioApplicationReq* to the CM with the handle of an installed radio application package.
- The CM deactivates the radio application instances (in case there are active ones), deletes them if necessary, and then performs uninstallation.
- The CM replies with *UninstallRadioApplicationCnf*.

10.1.3 Create radio application instance

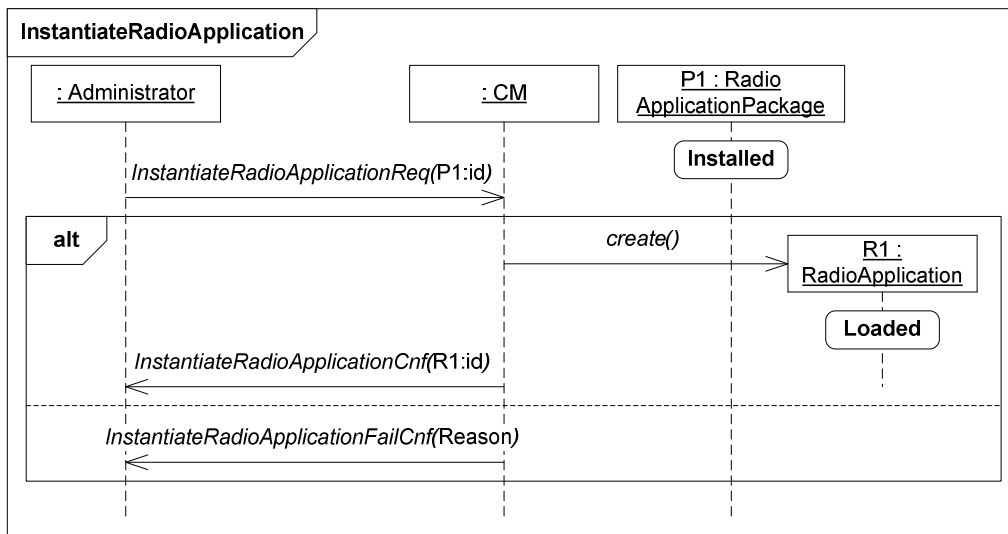

Figure 16: Instantiate radio application signalling diagram

The radio application instantiation procedure goes as follows:

- The Administrator user sends *InstantiateRadioApplicationReq* to the CM with the handle of an installed radio application package.
- CM evaluates the resource demand of the radio application and the limitations of the amount of instances, and creates a new instance if evaluation checks succeed.
- If the application instance is successfully created, CM replies with *InstantiateRadioApplicationCnf* including a handle (id) to the new radio application instance.

NOTE: This is different from the handle/identifier of the radio application package). Otherwise *InstantiateRadioApplicationFailCnf* is sent with appropriate reason why the instantiation failed.

10.1.4 Delete radio application instance

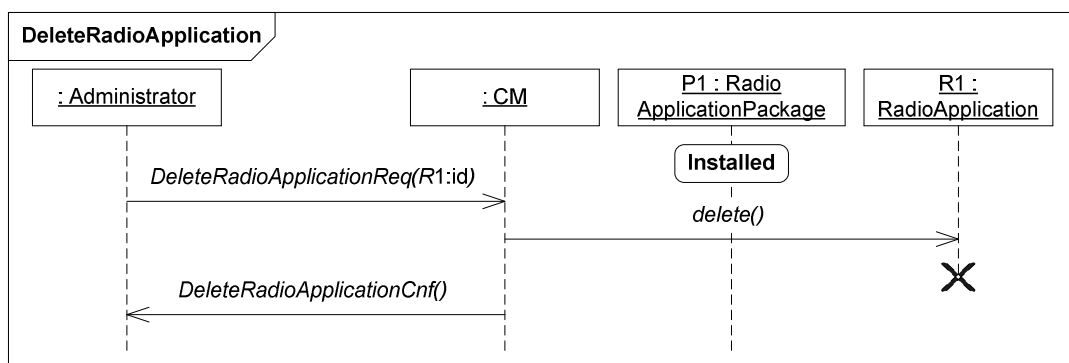

Figure 17: Delete radio application instance signalling diagram

The deletion of a radio application instance goes as follows:

- The Administrator user sends *DeleteRadioApplicationReq* to the CM with the handle of a radio application instance.
- The CM deactivates the radio application instance (in case it is active), and then deletes the instance.
- The CM replies with *DeleteRadioApplicationCnf*.

NOTE: Deletion of an instance cannot fail.

10.1.5 Get radio application parameters

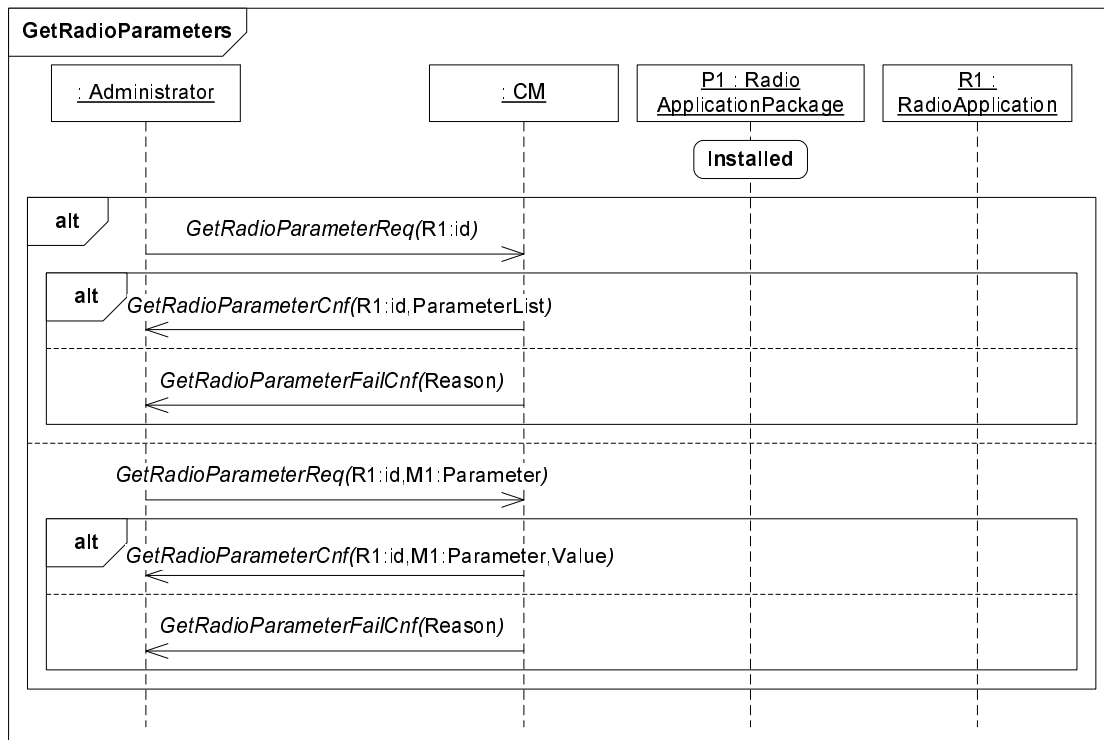

Figure 18: Get radio application parameters signalling diagram

The procedure of getting the parameters and parameter values of a radio application instance goes as follows:

- The Administrator user sends *GetRadioParameterReq* to the CM with the handle of a radio application instance along with the wanted parameters (or none, if all parameters are desired).
- CM evaluates the existence of the instance and the parameters, and the values of the parameters.
- If successful, CM replies with *GetRadioParameterCnf* including the parameters and their values. Otherwise *GetRadioParameterFailCnf* is sent with an appropriate failure reason.

10.1.6 Set radio application parameters

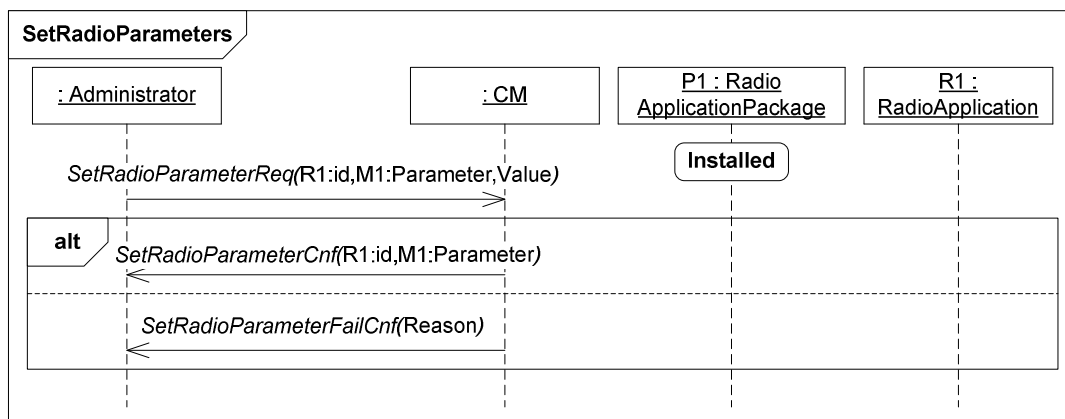

Figure 19: Set radio application parameters signalling diagram

The procedure of setting the parameters and parameter values of a radio application instance goes as follows:

- The Administrator user sends *SetRadioParameterReq* to the CM with the handle of a radio application instance along with the wanted parameters and their new values.
- CM evaluates the existence of the instance and the parameters, and that the values of the parameters are within the capabilities (bounds).
- If successful, CM sets the new parameter values and replies with *SetRadioParameterCnf*. Otherwise *SetRadioParameterFailCnf* is sent with appropriate reason why the setting failed.

10.1.7 List radio applications

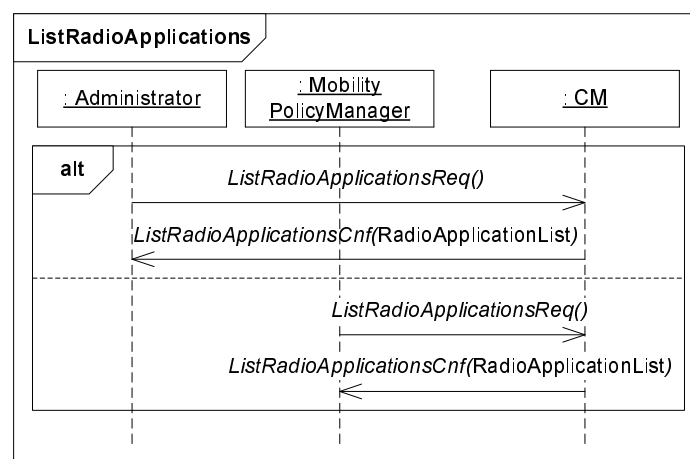

Figure 20: List radio applications signalling diagram

The procedure of listing the radio applications available in the multiradio computer goes as follows:

- The Administrator or the Mobility Policy Manager user sends *ListRadioApplicationsReq* to the CM.
- CM checks the installed radio applications, their instances and administrative states, and returns this information with *ListRadioApplicationsCnf*.

10.2 Access control services

Access control services represent the multiradio control plane functionality, and are available for radio application instances, not for radio application packages. Further, other access control services than activation are only available for active radio application instances. The Radio Connection Manager of the mobile device reference architecture provides these services.

Three categories of access control services are available: monitoring the radio environment and discovering peer communication equipment, establishing associations to these peer communication equipment, and establishing user data flows to the associations (including moving of data flow from one association to another, within restrictions, possibly even to an association of another radio application).

10.2.1 Activate a radio application instance

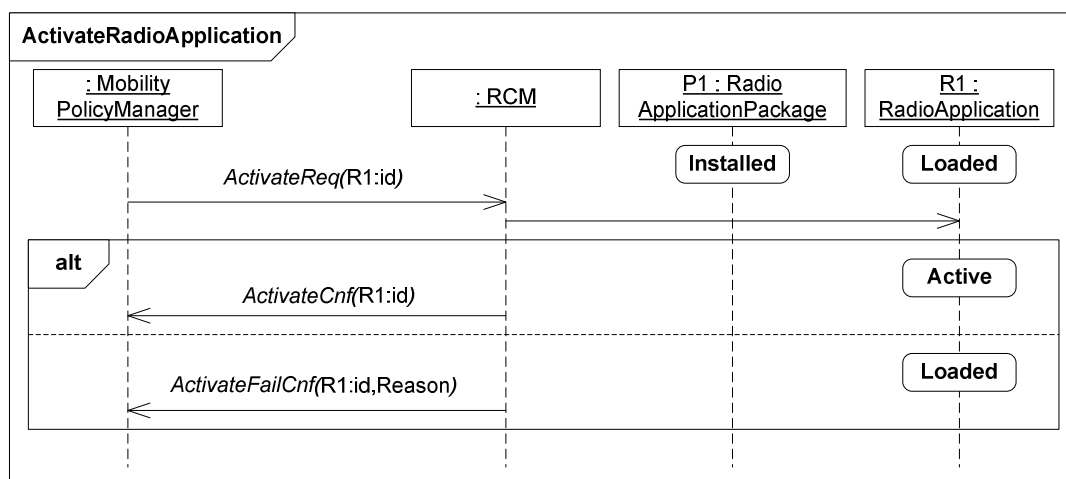

Figure 21: Activate radio application instance signalling diagram

The activation procedure of a radio application instance goes as follows:

- The Mobility Policy Manager user sends *ActivateReq* to the RCM with a handle of a radio application instance.
- RCM checks the administrative state of the application instance, and tries activation if the instance is not yet active. If the activation is successful, *ActivateCnf* is returned to the Mobility Policy Manager, otherwise *ActivateFailCnf* is sent with the reason of failure indicated.

NOTE: The activation of the radio application might fail due to resource limitations.

10.2.2 Deactivate a radio application instance

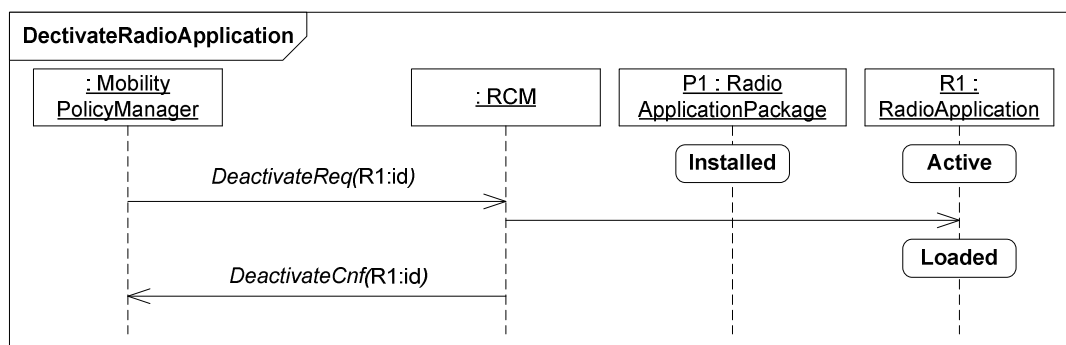

Figure 22: Deactivate radio application instance signalling diagram

The deactivation of a radio application instance goes as follows:

- The Mobility Policy Manager user sends *DeactivateReq* to the RCM with a handle of an active radio application instance.
- RCM checks the administrative state of the application instance, and deactivates it if active. *DeactivateCnf* is returned to the Mobility Policy Manager.

NOTE: The deactivation of the radio application always succeeds.

10.2.3 Start radio environment measurements

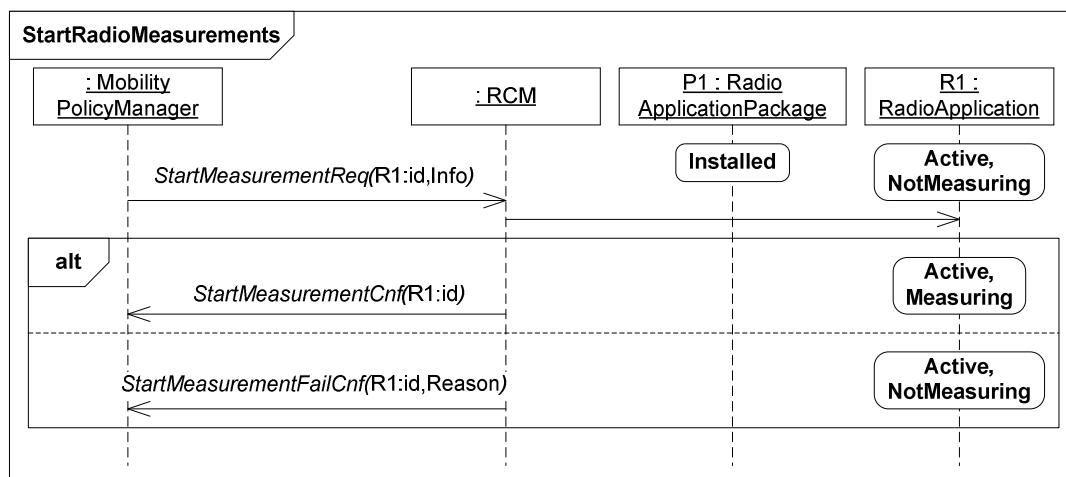

Figure 23: Start radio measurements signalling diagram

Radio environment measurements may be started and stopped. The starting procedure goes as follows:

- The Mobility Policy Manager user sends *StartMeasurementReq* to the RCM with a handle of a radio application instance, and any additional information about the measurements requested (e.g. spectrum measurement, peer devices to be discovered).
- RCM verifies that the application instance is active, and propagates the request to the application. If the measurements are started successfully, *StartMeasurementCnf* is returned to the Mobility Policy Manager, otherwise *StartMeasurementFailCnf* is sent.

NOTE: The radio application may do any measurements according to its technology specifications autonomously without a separate request from the user. This service is in that sense informative to the radio application; the user only states which kind of information it is interested in. The multiradio computer is obliged to provide the measurement results and discovered peer devices to the user by the procedure shown in clause 9.2.6.

10.2.4 Stop radio environment measurements

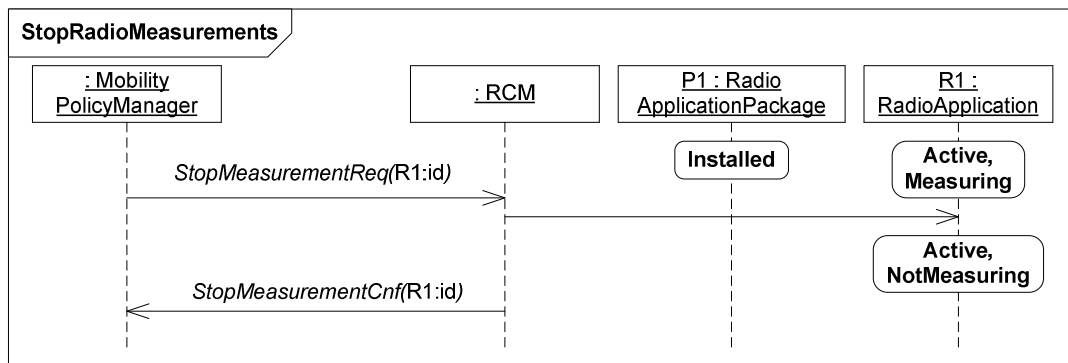

Figure 24: Stop radio measurements signalling diagram

The procedure of stopping radio environment measurements goes as follows:

- The Mobility Policy Manager user sends *StopMeasurementReq* to the RCM with a handle of a radio application instance.
- RCM verifies that the application instance is active, and propagates the request to the application. *StopMeasurementCnf* is returned to the Mobility Policy Manager. The procedure shown in clause 9.2.6 no longer takes place.

10.2.5 Radio environment measurement indication

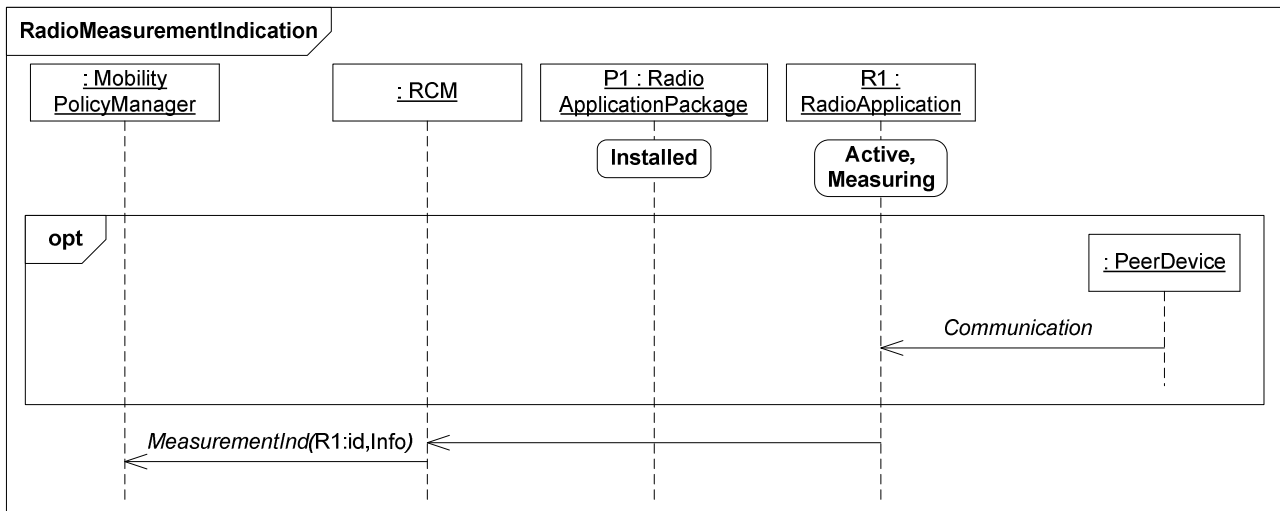

Figure 25: Radio measurement indication signalling diagram

The radio measurements are indicated to the user as follows:

- Radio measurement indications are only given if a user has requested the radio application measurements using *StartMeasurementReq*.
- Once measurement results are available, the RCM sends to the Mobility Policy Manager user *MeasurementInd* with the handle of the radio application instance, and the measurement information.

10.2.6 Create association with peer, mobile device originated

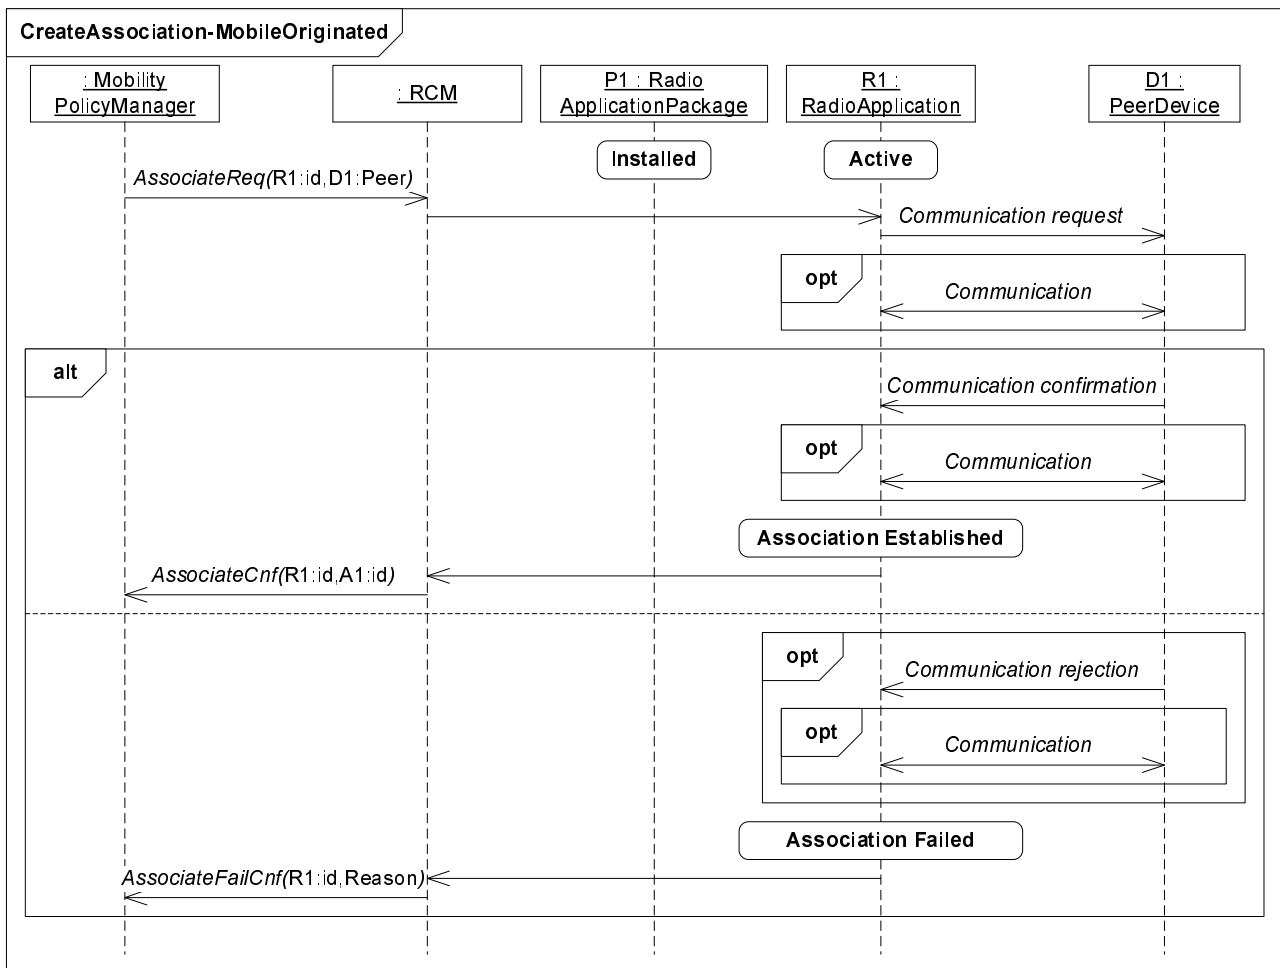

Figure 26: Create mobile device originated association signalling diagram

Establishing a mobile device originated association to a peer device goes as follows:

- The Mobility Policy Manager user sends *AssociateReq* to the RCM with a handle of a radio application instance, and the identification of the desired peer device.

NOTE 1: The identification of the peer device may be known through previous interactions, or by measurements done previously.

- RCM verifies that the application instance is active, and propagates the request to the application. The radio application tries to establish the association to the requested peer device.
- If successful, *AssociateCnf* is returned to the Mobility Policy Manager with an association identifier.

NOTE 2: this identifier is different from the radio application identifier. Otherwise *AssociateFailCnf* is sent along with a reason why the association failed.

10.2.7 Create association with peer, peer device originated

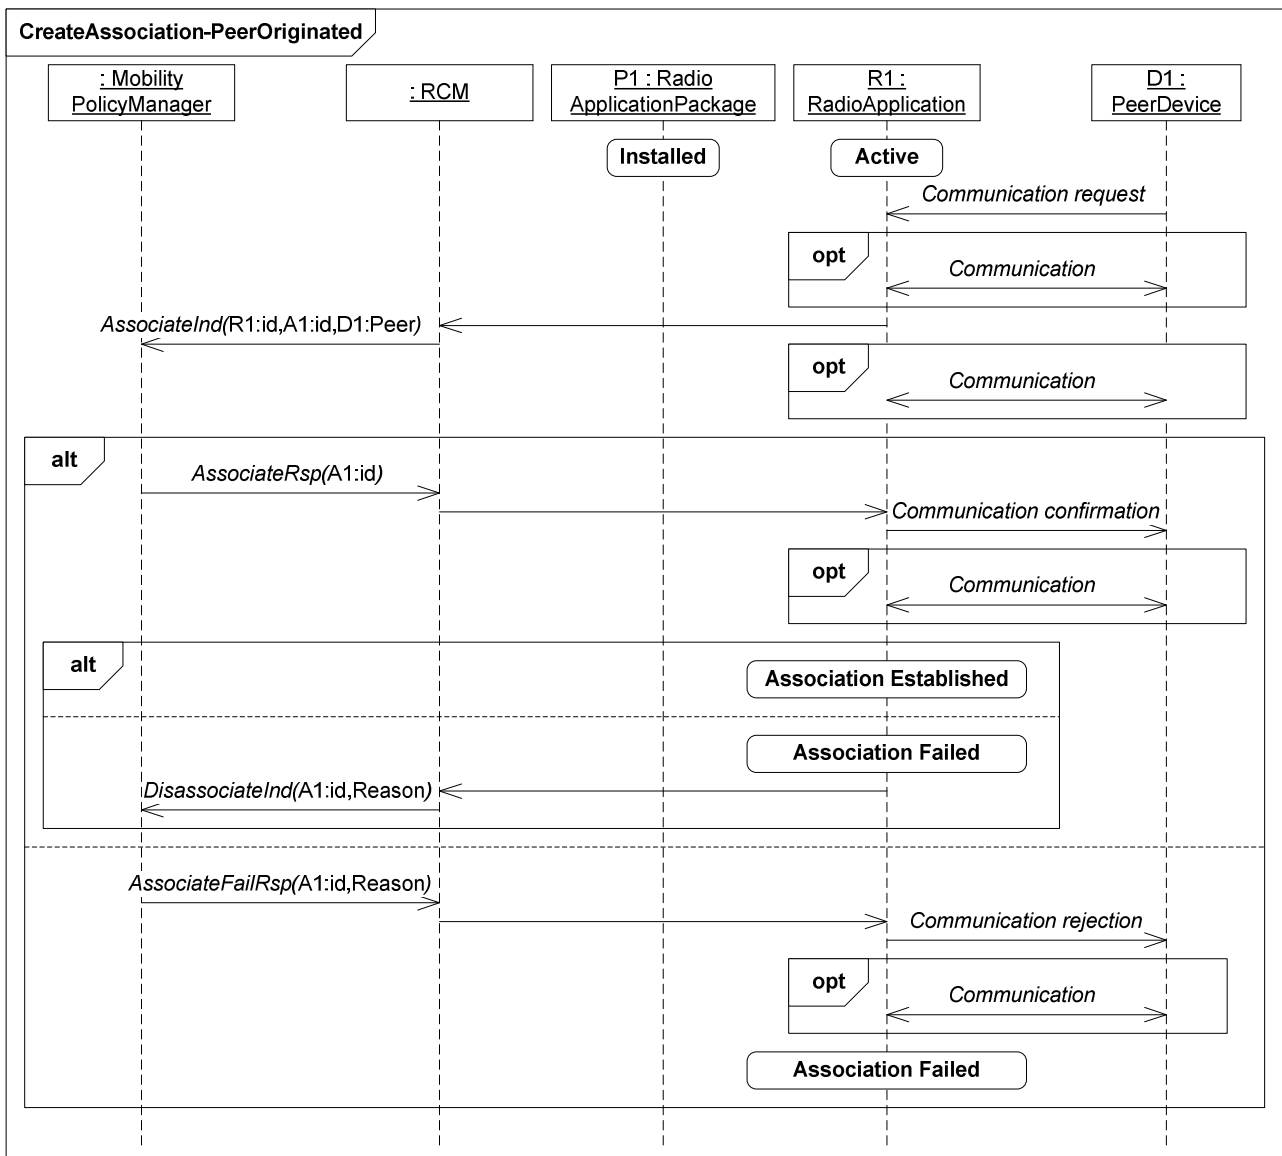

Figure 27: Create peer device originated association signalling diagram

Establishing a peer device originated association to a peer device goes as follows:

- The RCM sends an *AssociateInd* to the Mobility Policy Manager with the handle of the radio application instance, a handle to the association, and the identification of the desired peer device.
- The Mobility Policy Manager replies either with *AssociateRsp*, in which case the association will be established, or *AssociateFailRsp*, in which case the association is rejected.
- In case the association establishment fails after an *AssociateRsp*, RCM sends a *DisassociateInd* with reason of failure.

10.2.8 Terminate association, mobile device originated

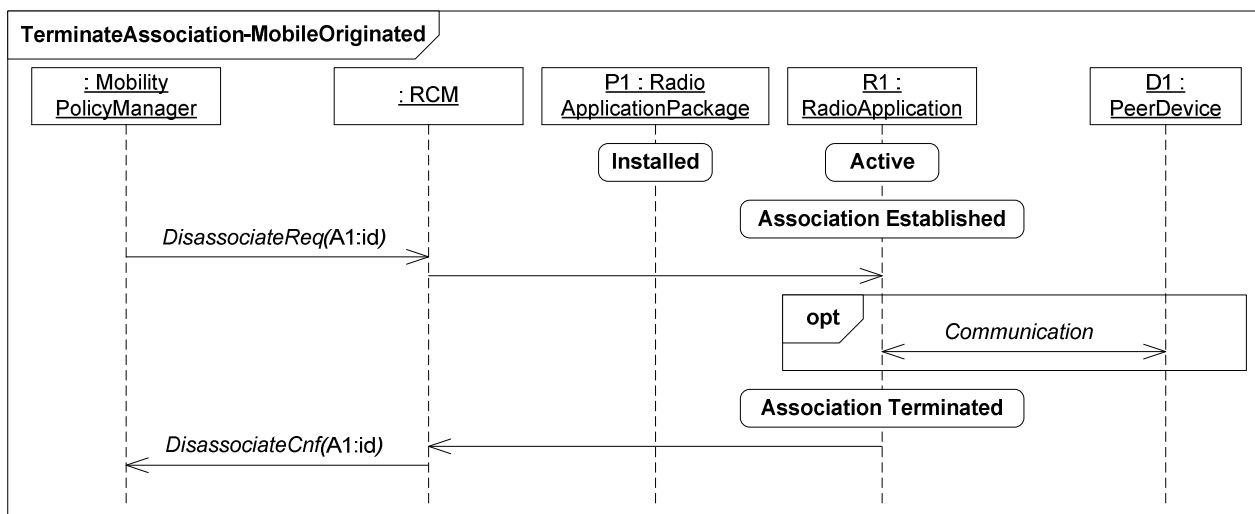

Figure 28: Mobile device originated disassociation signalling diagram

Terminating an association to a peer device goes as follows:

- The Mobility Policy Manager user sends a *DisassociateReq* to the RCM with a handle of the association.
- RCM verifies that the application instance is active, and propagates the request to the application. The radio application terminates the association. RCM returns *DisassociateCnf* to the Mobility Policy Manager.

10.2.9 Terminate association, peer device originated

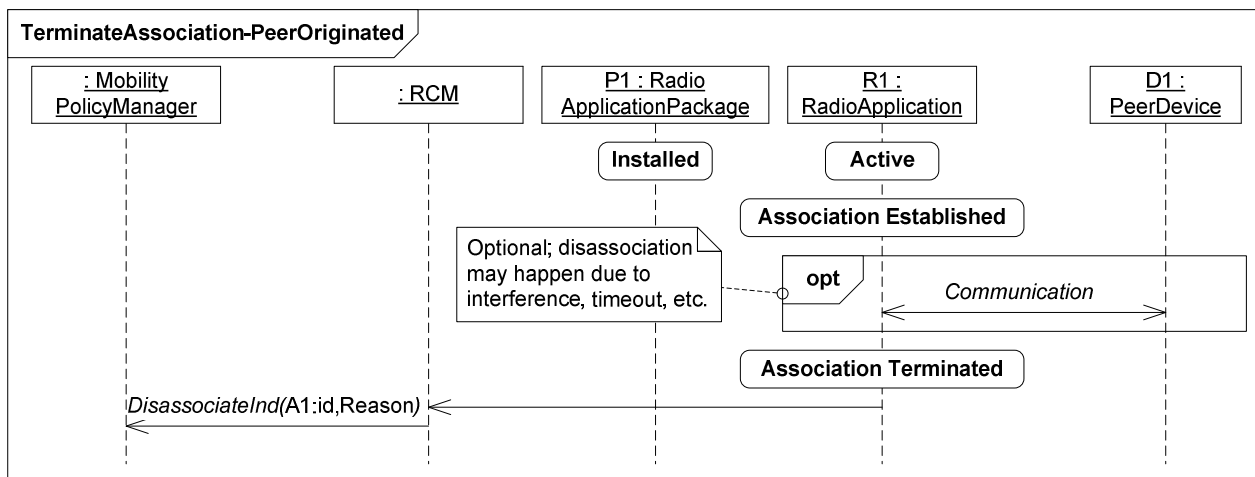

Figure 29: Peer device originated disassociation signalling diagram

Peer device originated termination of an association goes as follows:

- RCM sends a *DisassociateInd* to the Mobility Policy Manager with the handle of the association and a reason for disassociation.

10.2.10 Create data flow into association, mobile device originated

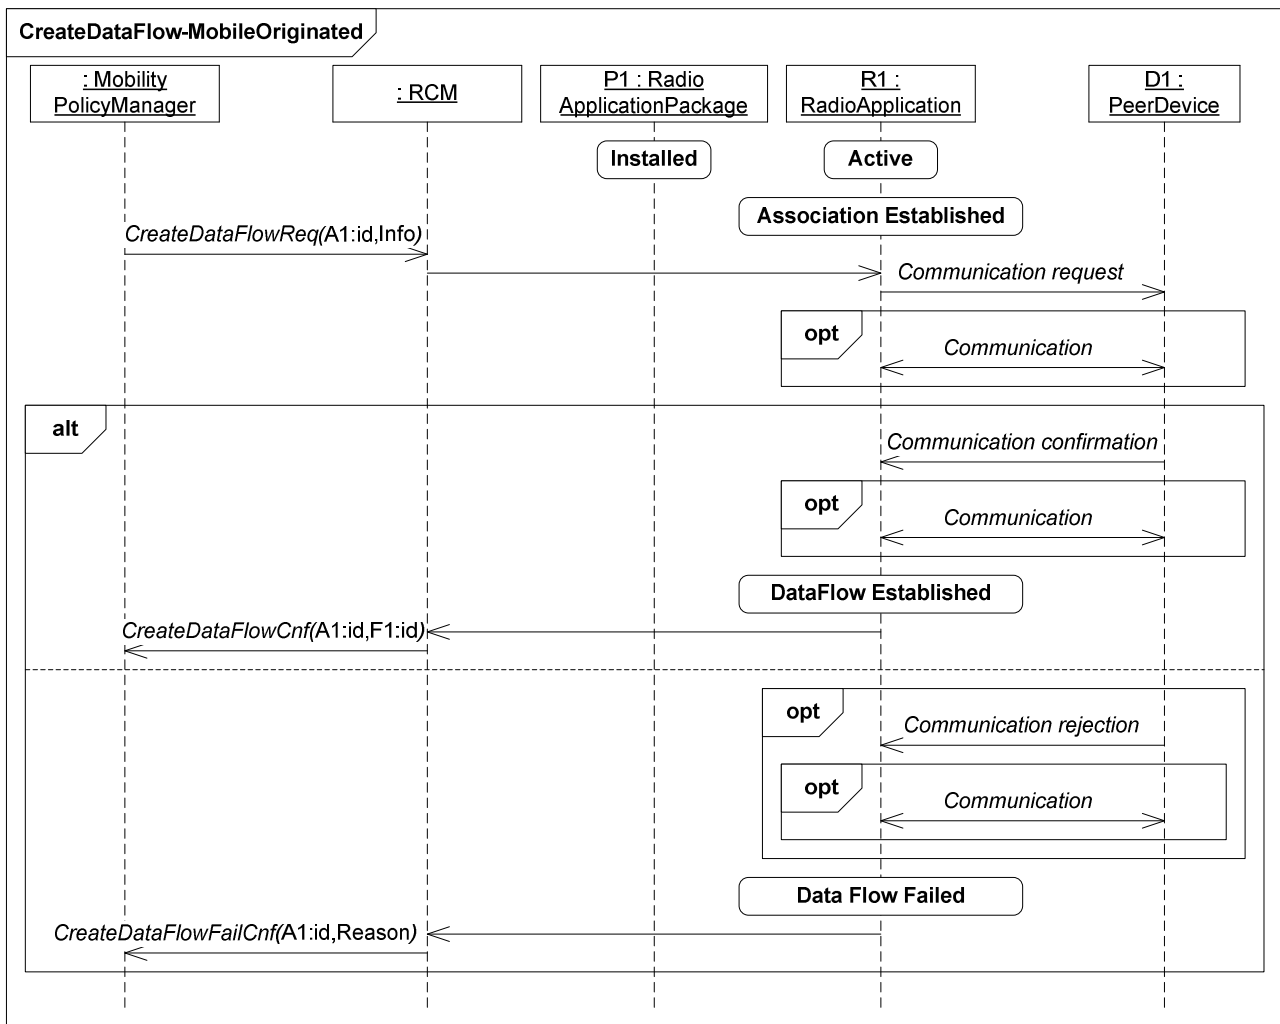

Figure 30: Create mobile device originated data flow signalling diagram

Establishing a mobile device originated data flow into an already present association goes as follows:

- The Mobility Policy Manager sends a *CreateDataFlowReq* to the RCM with the handle of an association and the information related to the requested data flow.
- RCM verifies that the application instance is active, and propagates the request to the application. The radio application tries to establish the data flow with the peer of the association.
- If successful, *CreateDataFlowCnf* is returned to the Mobility Policy Manager with a data flow identifier.

NOTE: This identifier is different from the association identifier. Otherwise *CreateDataFlowFailCnf* is sent along with a reason why the data flow establishment failed.

10.2.11 Create data flow into association, peer device originated

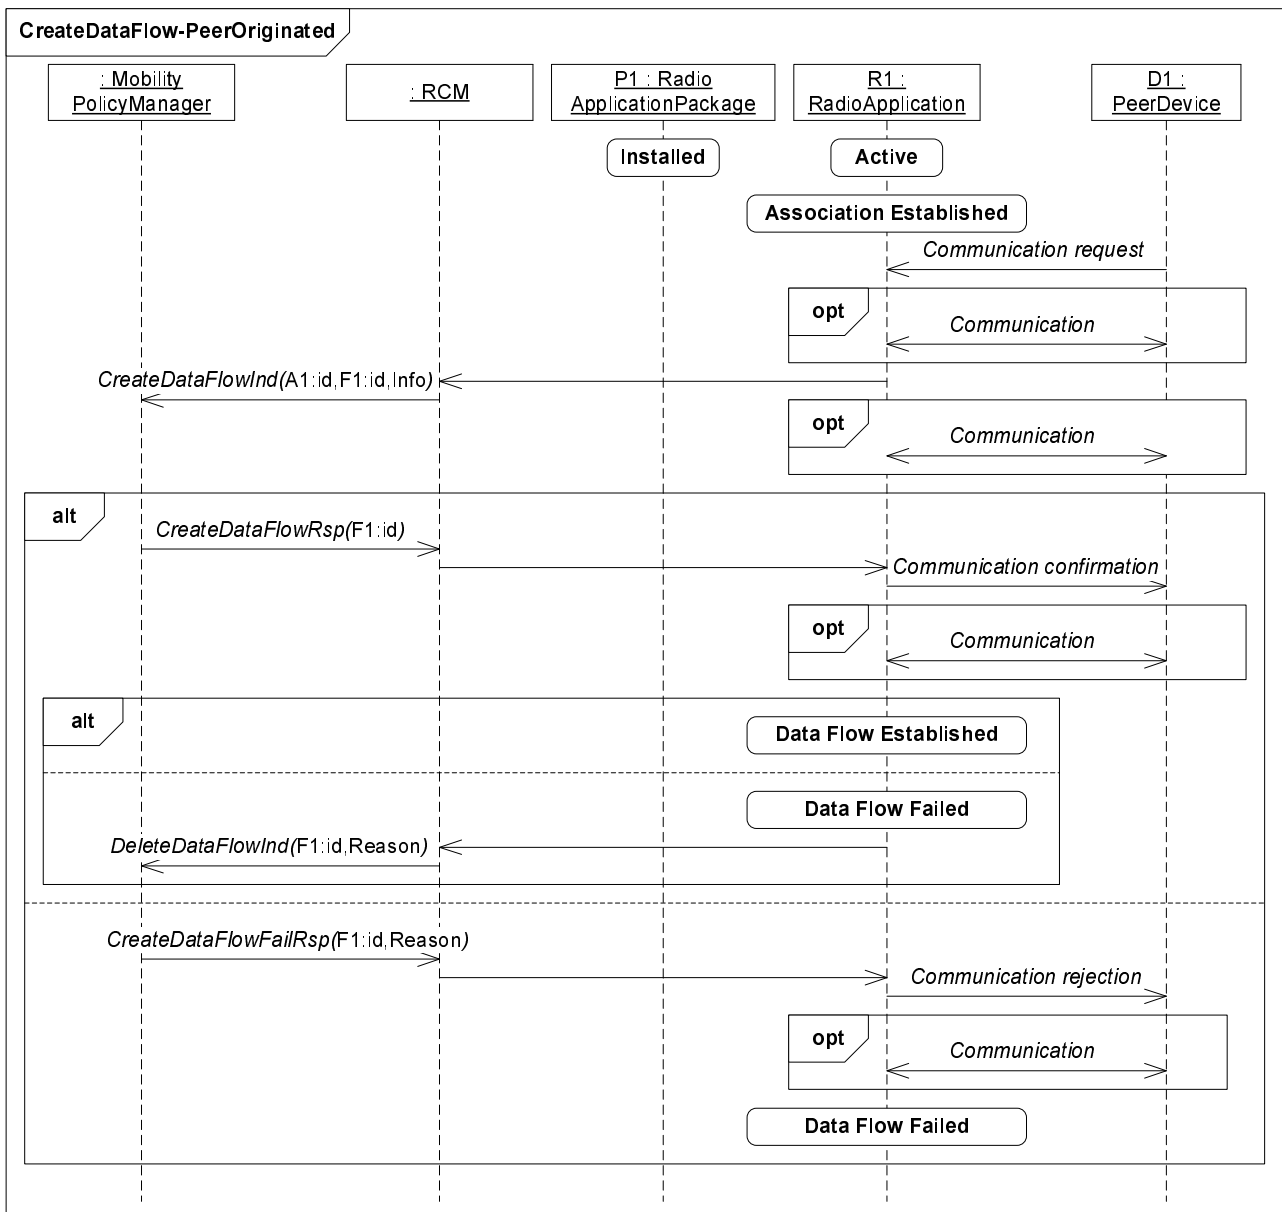

Figure 31: Create peer device originated data flow signalling diagram

Establishing a peer device originated data flow into an already present association goes as follows:

- The RCM sends a *CreateDataFlowInd* to the Mobility Policy Manager with the handle of the association, a handle to the data flow, and further information related to the data flow.
- The Mobility Policy Manager replies either with *CreateDataFlowRsp*, in which case the data flow will be established, or *CreateDataFlowFailRsp*, in which case the data flow is rejected.
- In case the data flow establishment fails after a *CreateDataFlowRsp*, RCM sends a *DeleteDataFlowInd* with reason of failure.

10.2.12 Terminate data flow, mobile device originated

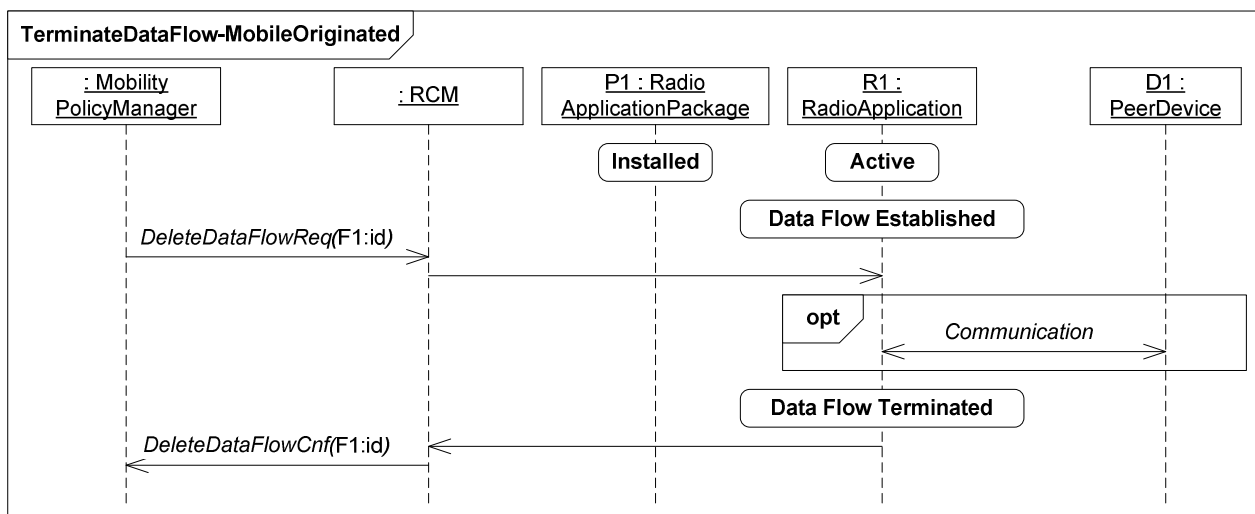

Figure 32: Mobile device originated data flow termination signalling diagram

Terminating a data flow from an association goes as follows:

- The Mobility Policy Manager user sends a *DeleteDataFlowReq* to the RCM with a handle of the data flow.
- RCM verifies that the appropriate application instance is active, and propagates the request to the application. The radio application terminates the data flow. RCM returns *DeleteDataFlowCnf* to the Mobility Policy Manager.

10.2.13 Terminate data flow, peer device originated

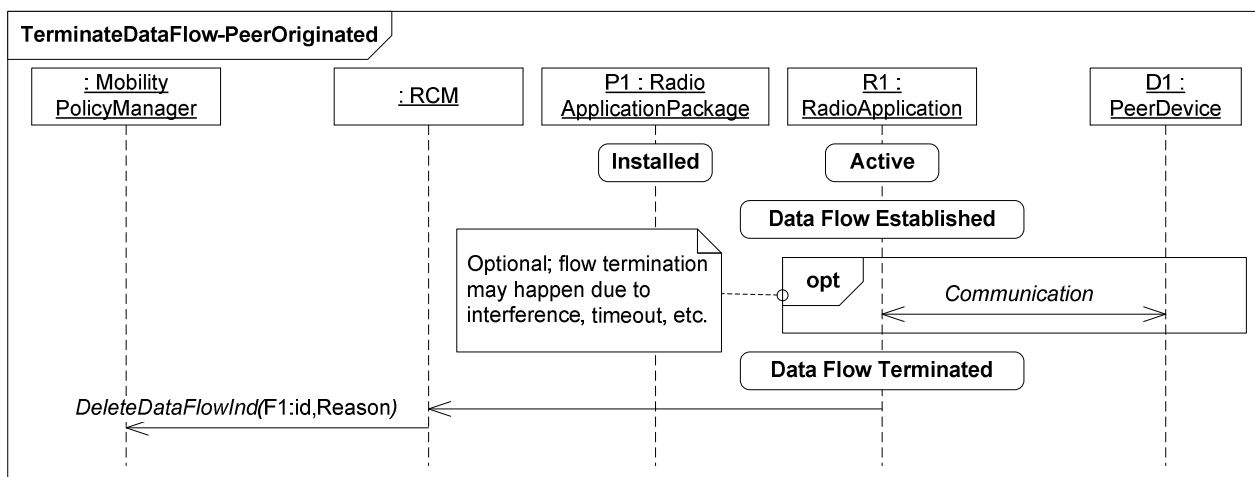

Figure 33: Peer device originated data flow termination signalling diagram

Peer device originated termination of a data flow goes as follows:

- RCM sends a *DeleteDataFlowInd* to the Mobility Policy Manager with the handle of the data flow and a reason for termination.

10.2.14 Move data flow from association into another

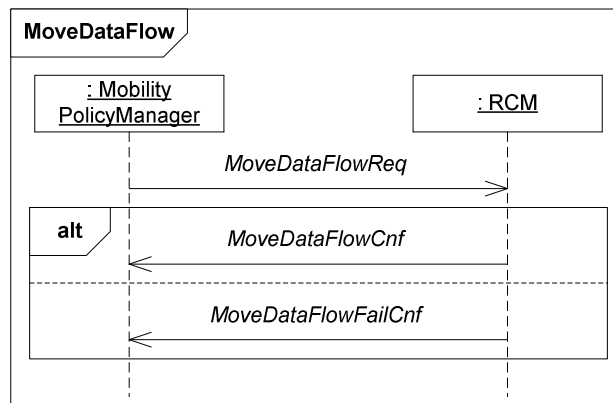

Figure 34: Moving of data flow from one association into another signalling diagram

The moving of a data flow goes as follows:

- The Mobility Policy Manager user sends a *MoveDataFlowReq* to the RCM with the handle of a data flow, and the handle of the association into which the data flow is to be moved.
- RCM verifies that the appropriate association exists, and moves the data flow to that association.

If successful, *MoveDataFlowCnf* is returned to the Mobility Policy Manager. Otherwise *MoveDataFlowFailCnf* is returned along with a reason why the moving failed.

10.3 Data flow services

10.3.1 Send user data

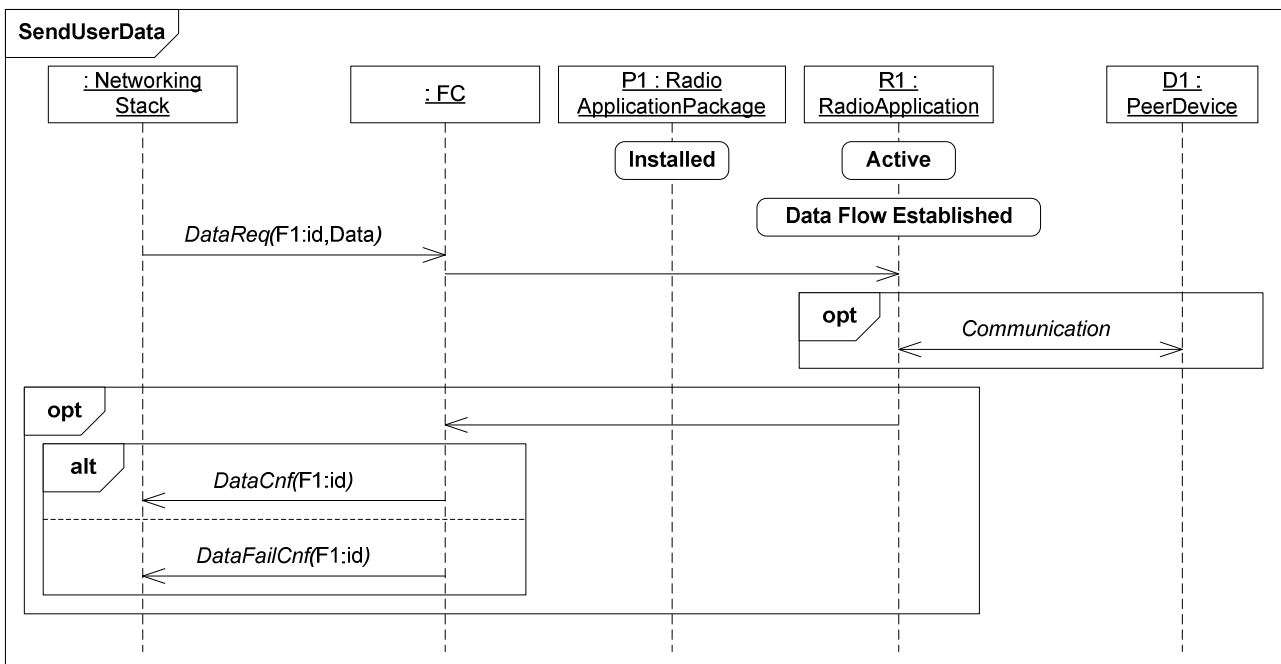

Figure 35: Send user data signalling diagram

Sending user data through an existing data flow goes as follows:

- Networking Stack sends a *DataReq* to the Flow Controller with the handle of the data flow, and user data to be sent.
- Flow Controller may respond with *DataCnf* or *DataFailCnf* depending on the success of the radio channel delivery (typically only Medium Access Control level acknowledgements are possible when using radio channel).

10.3.2 Receive user data

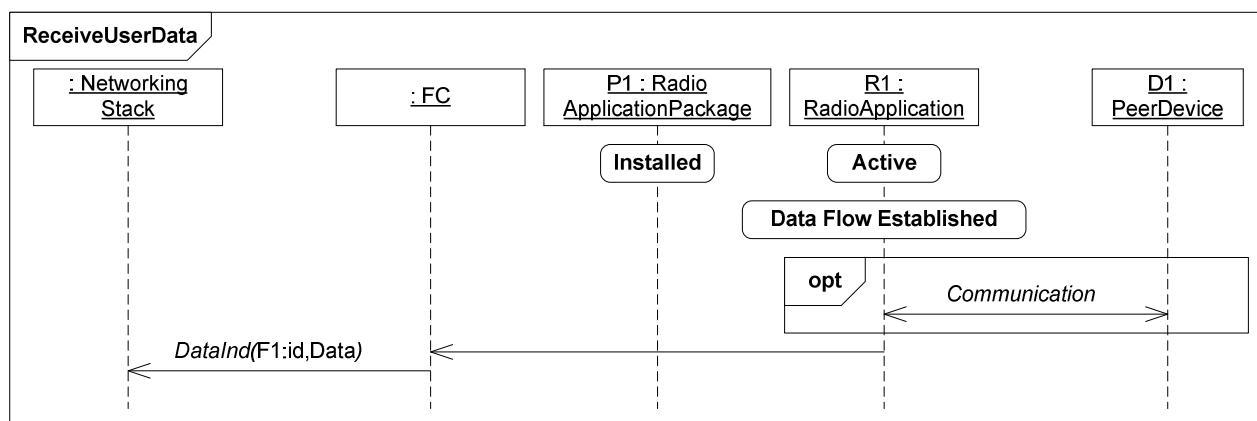

Figure 36: Receive user data signalling diagram

Receiving user data goes as follows:

- Flow Controller sends a *DataInd* to the Networking Stack with the handle of the data flow, and the received user data.
